Paper No. 1379

DESIGNING AN EARTH DAM HAVING A GRAVEL FOUNDATION, WITH THE RESULTS OBTAINED IN TESTS ON A MODEL*

By James B. Hays, Jun. Am. Soc. C. E.

With Discussion by Messrs. W. G. Bligh, J. C. Oakes, C. E. Grunsky, H. T. Pease, Malcolm Elliott, Edward Wegmann, E. C. La Rue, George M. Bacon, H. A. Petterson, D. C. Henny, Joseph Jacobs, and James B. Hays.

Synopsis.

The following paper, though giving the theory regarding the design of an earthen dam having a gravel foundation, is intended mainly to present the results of tests on a model constructed to scale. The dam was designed to impound water for storage purposes under rather unusual conditions. A study of the subject produced little of real value in determining the action of water under these conditions.

However, this paper does not give the detailed design of unimportant features but only the general design, especially the shape and type of cross-section and the quality of the materials placed therein.

It is hoped that the discussion will bring out many interesting facts and experiences which will contribute to more rational methods of design of earth dams, or of any dams, on porous foundations.

Introduction.

At the dam site in question, a dam had been started, but was wholly unfit to sustain even a small proportion of the head of water

* Presented at the meeting of April 19th, 1916.

required. The reservoir was for the storage of water for irrigation purposes, and the dam was to be 110 ft. high at the maximum section. With an approximate depth of 30 ft. of material in place, and nearly the whole width of the base, a head of slightly less than 25 ft. caused water to issue in considerable quantities from the down-stream toe of the dam. This caused the people living in a small town a few miles down the river to become fearful of the results.

Several reports, made by different engineers, unanimously condemned the structure as it was being built. The bonding house backing the irrigation company failed at this time, the project was sold to satisfy judgments, and the contractors for the dam took over the proposition.

At their request, F. C. Horn, M. Am. Soc. C. E., was asked to submit a design for a dam to be built at the same site, if it could be done, in order to utilize as much of the existing structure as possible. On account of the unusual conditions—which will be stated later—it was decided to make a thorough research, to be followed by experiments and tests, in order to make certain of the design. The writer did much of the research work, constructed the model, and made the tests for, and with, Mr. Horn, which the latter has kindly made available.

General Conditions.

The stream on which the dam was being built runs southeastward, and, on the southwest side of the valley there are high cliffs of cherty limestone near which the stream has its course. On the opposite side of the valley there are high mountains at some distance from the river. Mountain streams, rushing along at high velocity, had carried gravel, sand, and some boulders out into the valley bottom, where the material was dropped, forming great cones, or fans, of very porous material. The dam site had been originally selected having one of these gravel cones as the foundation and northeast bank, this being done with only a superficial knowledge of the subsurface conditions.

When trouble was reported, work was ordered stopped by the State Engineer; then a few borings were made and test pits dug, the results of which were available for the re-design of the structure. The borings, which were made close to the center line, or axis, of the dam, show that it would be practically impossible, and useless, to reach bed-rock throughout the entire length of the dam and thereby cut off the underground flow of water.

In the subsoil investigations, a material was encountered which was called hardpan. Chemical investigation shows that there is practically no clay in this material, and, in fact, no clay in the vicinity. The material called hardpan was very fine, gritty, and angular. It was tightly packed, and formed a very dense mass.

A large quantity of this fine material was found on the surface, about a mile from the dam, and when shaken down in a glass container, packed into a very tight, dense mixture. This material is often called hardpan, but is not real hardpan, as it contains no clay.

A cut-off wall of concrete was built across the river channel, beneath which steel sheet-piling was driven into this so-called hardpan. Some of the piling was driven 18 ft. deep, and other portions sank as deep as 32 ft. with one or two blows from a 1 700-lb. hammer.

The body of the dam was being built of the same material as that composing the gravel cone at its northeast end, and, as was shown in one of the reports, nearly all the water, except flood waters, of the creek that had con-

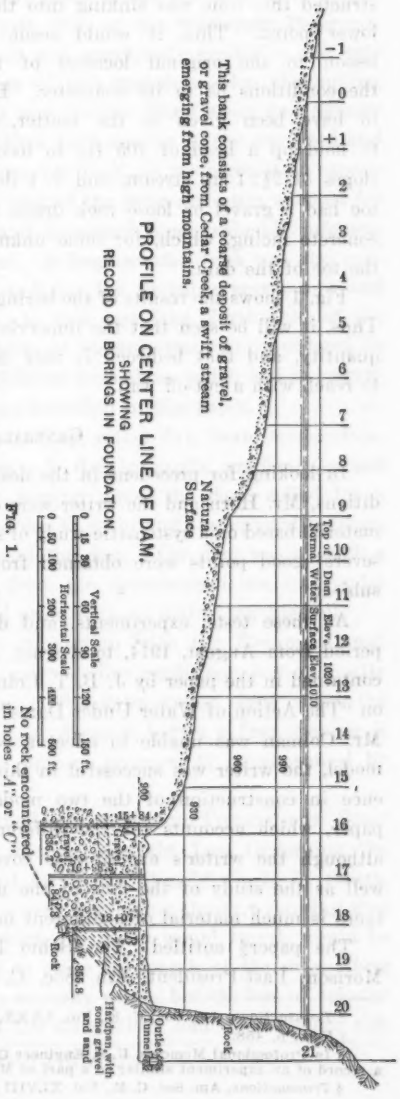

FIG. 1.

structed this cone was sinking into the gravel and reappearing at a lower point. This, it would seem, should have been an object lesson to the original locators of the site, and would indicate the conditions as to its character. However, little attention seems to have been given to the matter, and a dam was being built to hold up a head of 105 ft., to have a top width of 20 ft., with slopes of $2\frac{1}{2}:1$ up stream, and 2:1 down stream. The down-stream toe had a gravel or loose rock drain, and the up-stream face had a concrete facing, which, for some unknown reason, did not extend to the toe of the dam.

Fig. 1 shows the results of the borings on the center line of the dam. Thus, it will be seen that the impervious stratum is a very uncertain quantity, and that bed-rock is very deep and practically impossible to reach with a cut-off wall.

General.

In looking for precedent in the design of a dam under these conditions, Mr. Horn and the writer were confronted with a lack of good material based on a systematic study of structures of this type, although several good points were obtained from some of the papers on the subject.

As these tests, experiments, and designs were made during the period from August, 1914, to August, 1915, the valuable information contained in the paper by J. B. T. Colman, Assoc. M. Am. Soc. C. E., on "The Action of Water Under Dams",* was not available. Although Mr. Colman was unable to effect a complete loss of head with his model, the writer was successful in this, and has explained the difference in construction of the two models in his discussion† of that paper, which accounts for the different results obtained. However, although the writer's experiments cover the design of the dam, as well as the study of the flow of the underground water, he believes there is much material of a different nature contained in this paper.‡

The paper§ entitled "The Bohio Dam", by the late George S. Morison, Past-President, Am. Soc. C. E., contains some interesting

* *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 421.

† *Ibid.*, p. 458.

‡ In Professional Memoirs, U. S. Engineer Corps, Vol. VII, p. 44, par. 33, there is a record of an experiment similar to a part of Mr. Colman's.

§ *Transactions*, Am. Soc. C. E., Vol. XLVIII, p. 235.

points, and the discussion on that paper brings out some good details regarding the design of the North Dike of the Wachusett Reservoir. In this structure a deep trench was excavated parallel to the axis of the dam, and in the bottom of this trench wooden sheet-piling (some pieces as long as 60 ft.) was driven. Percolation and seepage experiments were conducted with a tank similar to the one used and described by Allen Hazen, M. Am. Soc. C. E., in his percolation experiments. In the case in hand, a tank of the same style was adopted for the preliminary experiments, and furnished much valuable information to be used in the final tests. A large wooden tank was also constructed for the purpose of studying the probable percolation and seepage through the structure. In this case (the North Dike of the Wachusett Dam), the foundation, or subsoil, was not considered in the tests; thus the conditions differed from those which had to be considered in the design of the dam described in this paper.

In the North Dike there was a long, rather flat, down-stream slope, and a steeper up-stream slope. A flat hydraulic gradient, caused by the water in the reservoir seeping under the dam, called for a large quantity of material, in order to withstand the upward pressure under the down-stream portion of the dam. The dam was of such a length that the water, rising from the down-stream toe, was under no upward pressure and flowed away without disturbing the soil.

The Gatun Dam, built in connection with the Panama Canal, was designed and constructed under similar conditions, having a silty river deposit for a foundation. A flat down-stream slope causes the percolating water to travel a long distance before a free opening is encountered, thus causing the upward pressure to be consumed by friction.

In discussing the paper entitled "Dams on Sand Foundations: Some Principles Involved in Their Design, and the Law Governing the Depth of Penetration Required for Sheet-Piling",* G. E. P. Smith, M. Am. Soc. C. E., works out a very interesting theory,† showing that the creep, or total distance which the water would travel, would be increased by an amount equal to twice the length of the sheet-piling introduced. It is not stated in so many words, but the loss of velocity in traveling down one side of the sheet-piling and up the other side

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 175.
† *Ibid*, p. 197.

amounts to the same as adding twice the length of the sheet-piling to the length of the base.

W. G. Bligh, M. Am. Soc. C. E., gives a very interesting treatment of the design of weirs on sand foundations.* His theory is that the water will follow the line of creep, along the base of the dam, down one side of the cut-off wall, up the other side, and continue along under the base to a free outlet, that is, that pressure is lost in direct proportion to the enforced line of creep. This theory gives structures of ample dimensions, as has been shown by practice, but was found to be incorrect, after due experimenting, as will be noted later.

E. A. Moritz, Assoc. M. Am. Soc. C. E., has given† the customary method followed by the United States Reclamation Service Engineers. This, it will be noted, follows the line of creep theory as described by Mr. Bligh.

D. C. Henny, M. Am. Soc. C. E., made tests‡ on different combinations of the available local materials in order to determine the tightest mass. Tests for seepage were made with many different mixtures.

In the writer's method, only one combination of materials was made, and that was done by a study of the sieve analysis curves.§ Such curves are plotted for the various materials at hand, and compared with the ideal curve for the densest mass. Experience has proved that this method gives a very tight concrete. The experiments described in Mr. Henny's paper did not cover the seepage under the dam, but adequate drainage was provided in order to forestall the danger of the down-stream bank sloughing off.

Experiments and Tests.

The foregoing sources of information are mentioned in order to show what materials were available, to give credit where similar plans were followed, and, for the sake of comparison, to state where results differed, which was largely the case.

† "Working Data for Irrigation Engineers", pp. 39–40.

‡ "Two Earth Dams of the United States Reclamation Service", *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 38.

§ This method is explained in Taylor and Thompson's "Concrete, Plain and Reinforced", pp. 194, *et seq.*

The first experiments were for the purpose of determining the loss of head due to the water percolating through the various materials.

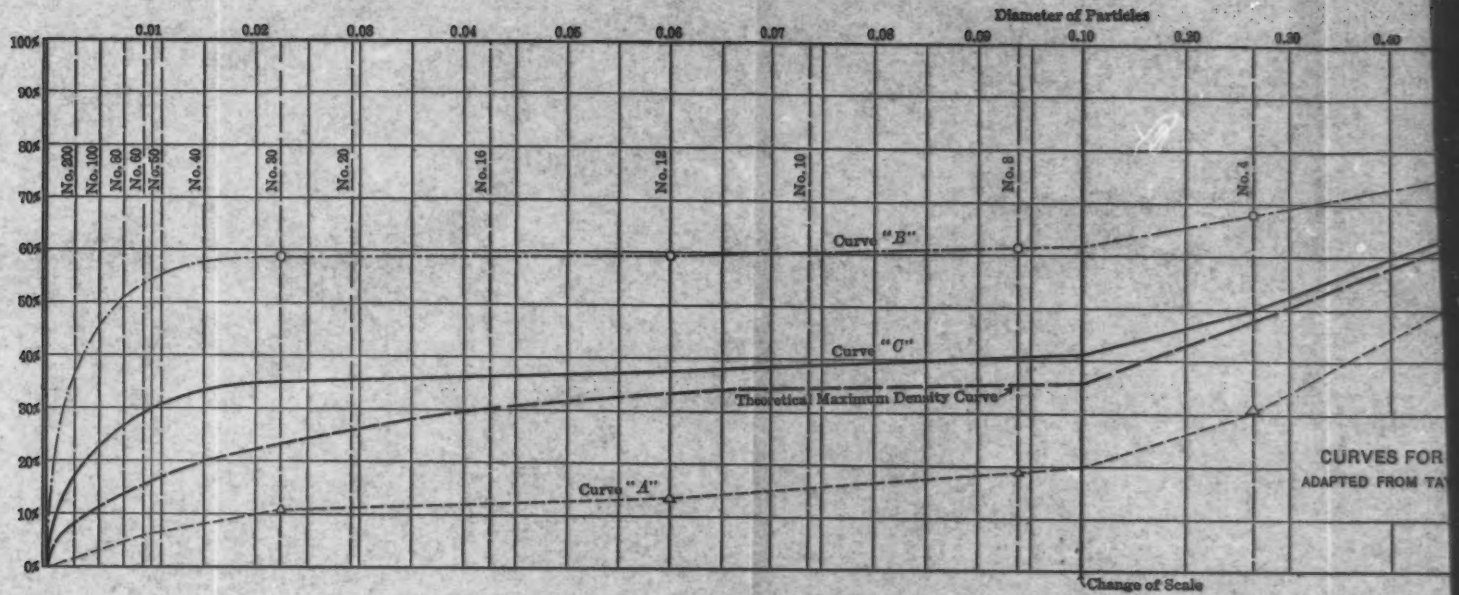
In the first test the attempt was made to determine the hydraulic gradient, or loss of head, through the coarse material constituting the foundation of the dam, and of which a part of the structure was already built. The tank had a diameter of 30 in., and a total height of 5 ft. The inside of the tank was given two coats of paint, and was then sanded in order to prevent possible seepage along its walls. Two glass tubes extending upward on the outside of the tank were connected with the inside and arranged to indicate the loss of head between two points which were vertically distant 3 ft. Fig. 2 shows the tank. A valve at the bottom held back the water until the pore spaces were completely filled; then the valve was opened, and after a few minutes the relative elevation of the water in the two tubes became constant. The difference in elevation determined the loss of head, and from this the hydraulic gradient was computed.

The initial run gave a very small loss of head; a few days later, the loss was greater and remained constant. This is explained by the fact that the material was placed in the tank in a dry state and the first application of water readjusted the finer materials into what in all probability represents the natural condition. With 6 in. of water on the soil surface, and 8 in. of soil above the upper tube, the loss of head was 1 ft. in 9.

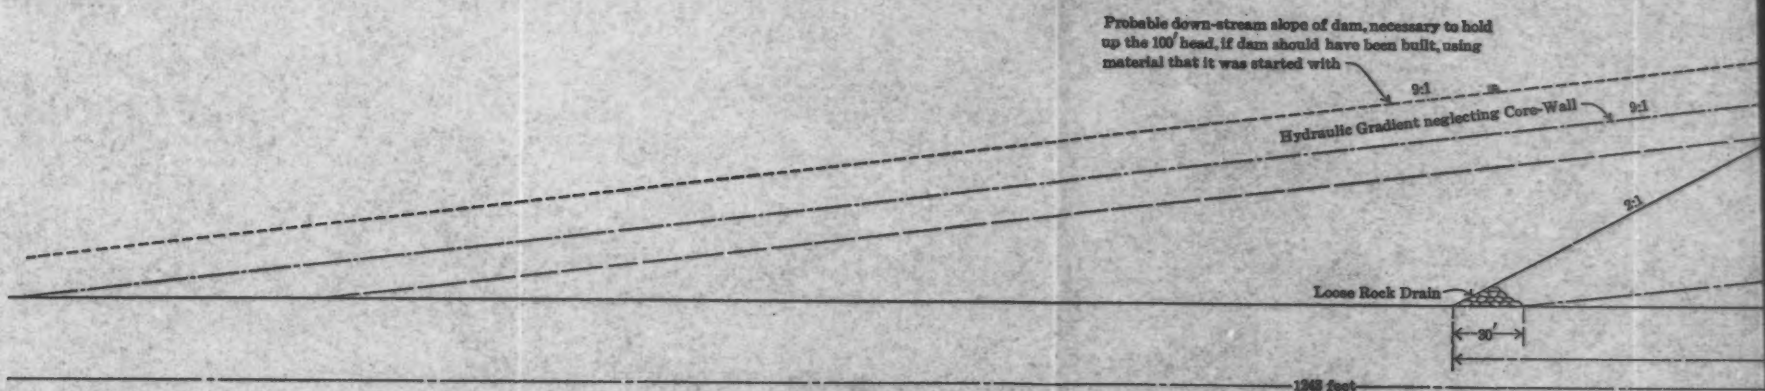
This gravel was screened into its various sizes, and showed a very small percentage of fine material. In the upper diagram on Plate I, Curve *A* shows this material as plotted. Fig. 3 is reproduced from a photograph of a sample of this material, and Fig. 4 shows the material as it stood in the steam-shovel pits from which the dam was being constructed and from which point the sample was taken.

Having determined the hydraulic gradient of the underground material, a trial design was made to find what dimensions would be necessary in a dam constructed wholly of this gravel. The lower diagram on Plate I shows the dimensions, assuming that the hydraulic gradient began at the water surface on the up-stream face of the dam. The effect of the core-wall on the "line of creep" theory would be small. The section shown was deemed to be very inefficient and excessively expensive, on account of the large quantity of material

to be placed. Further investigations were then made to determine how the section could be reduced.



Following out the "line of creep" theory as the one which seemed to be more nearly correct, on account of its practical success, it was decided that, if a tight material could be obtained for the up-stream section, the hydraulic gradient could be forced to begin farther up stream, and thus there would be secured the advantage of the up-stream section in reducing the upward pressure before the water reached the portion of the dam below the center line or core-wall.



As mentioned previously, a large body of very fine material was available in the vicinity. A sample of this material when analyzed gave Curve *B* in the upper diagram on Plate I. Curve *A* showed a lack of material, which was just balanced by the excess of fine material in Curve *B*. By observation, it was determined that, for all practical purposes, the combination of these two materials in the ratio of 1:1, would give a very dense mixture which would approach closely the ideal curve. Curve *C* represents the combined material. Fig. 5 shows a sample of the fine material, and Fig. 6 shows the combined material.

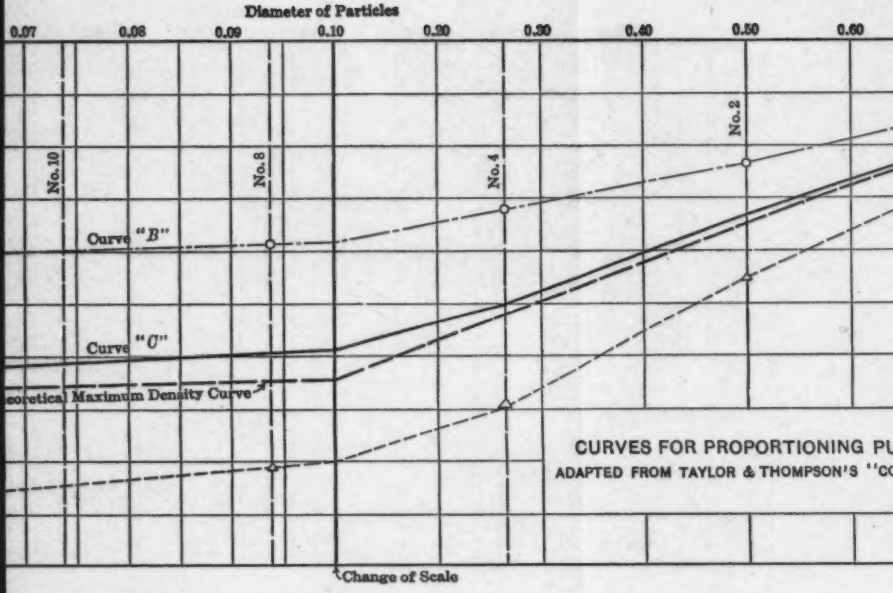


TABLE 1.—MECHANICAL AND CHEMICAL ANALYSES OF THE FINE MATERIAL OBTAINED ONE MILE FROM THE SITE OF THE PROPOSED DAM.

MECHANICAL ANALYSIS. This analysis covers only the material remaining on, and passing, the 30-mesh sieve.			CHEMICAL ANALYSIS. Air-dried sample.

during the first day. In the morning of the second day, fully 80% of the water was still on the surface, and at the end of 47 hours both tubes were filled with water, though the valve at the base had been closed for the entire period.

On proceeding with the tests it was found impossible to determine the exact hydraulic gradient, as no water appeared in either of the tubes shortly after the valve was opened. From this it was assumed that the hydraulic gradient was not greater than 1:1, although it was evidently much steeper. Hence the design was made on this basis.

This structure was designed by following out the "line of creep" theory, and it was calculated that, for a head of 100 ft. of water in the reservoir, a line of creep of 900 ft. would be necessary at the maximum section. By using the combined materials in making the up-stream section, in order to secure water-tightness, and avoid the transmission of the water pressure through the up-stream section in any great amount, it was assumed that the hydraulic gradient could be made to begin at or near the up-stream toe of the dam. Then, by the introduction of sheet-piling, the length of the base could be determined. Two rows of sheet-piling were at first suggested, and these could be made very effective by driving them in the bottom of trenches excavated for the purpose. Concrete core-walls over the piling would provide an adequate cut-off to prevent the water from passing over it. The design shown in Fig. 8 was then prepared for test. The long up-stream slope was given in order to allow the downward pressure of the water over the up-stream section to have a balancing effect on the upward pressure beneath the dam, as blow-outs would be improbable in this portion of the dam. This also gave a drier down-stream section, which meant a larger factor of safety from sloughing off and the like. A theoretical grade line is shown applied to the design.

Then, for the final tests, a model was constructed to the scale of 1 in. to 10 ft., and a large wooden tank of the dimensions shown in Fig. 8. All joints were caulked and filled with a composition filler, and then the whole interior was given two coats of a water-proof roof paint. On the second coat sand was applied, in order to prevent possible leakage along the walls. The glass tubes were placed at the points indicated by letters. They communicated by pipes with the interior of the mass at two points, and were set in from the sides of the box in order to avoid percolation along the walls. At the down-

stream end of the tank there was an overflow and also a drain. A width of 4 in. at the end of the box was filled with very coarse gravel, and this was separated from the remaining gravel by a coarse cloth. This allowed the water to travel in straight lines to the end of the box, and did not tend to force the water up to the ground surface unnaturally.

Several of the glass tubes were intended to indicate the upward pressure of the water on the base of the dam, and the others were placed along the bottom of the box to show the influence of the sheet-piling on the flow of water at the deeper points.

From the information at hand it was assumed that the bed-rock would not be more than 240 ft. below the base of the dam under the maximum section. The up-stream toe of the dam was then placed about 43 in. from the head of the box. In this way there would be plenty of room for the water to get into the soil; in other words, it was deemed necessary to avoid a narrow section or constriction through which the water would have to be forced, thereby causing a greater loss of head. A space of 3 ft. was left on the down-stream side of the dam to permit the water to come up to the surface; this was thought to be sufficient when the vertical loose-rock drain was allowed at the end.

All the subsoil material was placed dry, which made it necessary to disregard the first few readings. More than thirty readings were taken, and consisted of several runs, at four or five different heads above the dam. Records were kept of the quantity of water seeping through the gravel bed; these are given in the last column of Table 2.

Fig. 10 shows typical results obtained in the first series of tests. It will be noted that the loss of head does not follow the rule regarding the line of creep. This is shown particularly at the upper row of sheet-piling, where the loss of head is very small and not in proportion to the length of the sheet-piling. At the lower row of sheet-piling, however, near the center line of the dam, the loss of head is far greater in proportion than that at the upper row.

According to the theoretical hydraulic grade line shown on Fig. 8, the loss of head due to the upper row of sheet-piling would be, following the "line of creep" theory, 7.2 ft., though it was actually from 3.5 to 5 ft., only. The theoretical loss at the second or longer row of sheet-piling was calculated to be 9.4 ft., and the actual loss was more than twice as much, or from 19 to 21 ft.

* This column gives the seepage or percolation, in cubic feet per second per linear foot of model dam.

† Experiments were taken with water receding in order to compare with others; also, no percolation readings were taken.

‡ Figures excessive, due to water breaking through up-stream section of model dam.

NOTE.—The figures in this table may be converted to inches by pointing off one place and reading direct, thus 17 equals 1.7 in.

The writer wishes to state at this point that where the figures were given in feet, for convenience in stating the case relative to the actual structure, they represent actually tenths of inches on the model, that is, 19 ft. as stated above was 1.9 in. measured on the model. The figures given in the preceding paragraph were for a full head (10 in. equals 100 ft.).

The hydraulic grade line, represented by the upper row of tubes, indicated that there was an appreciable loss of head at the down-stream toe of the dam, and the lower row of tubes showed a complete loss of head at Tube *K*.

Fig. 10 (*b*) shows the hydraulic grade line of the lower row of tubes when the distance is computed from the up-stream toe of the

dam to each tube directly, and it will be noted how close the hydraulic gradient is to a straight line. Tube *J* was evidently affected by the sheet-piling to some extent.

Fig. 10 (*c*) shows the seepage loss from the body of water above the dam. This subject will be discussed later.

The failure of the "line of creep" theory to work out on the model as it was expected, caused the development of another theory as to the effect and usefulness of sheet-piling as a cut-off, preventing or reducing the underground flow of water in dams designed or built under similar conditions.

The theory finally evolved was that the sheet-piling cut-off was greatly similar in its effect to a partly closed valve, wherein the water is retarded and shows a higher pressure head just above the cut-off and a lower one just below. This theory is well known in regard to the hydraulic gradient of a pipe line, and explains the inefficiency of the upper row of sheet-piling as a cut-off. Hence, in the final design of the dam, this upper or shorter row of sheet-piling was omitted, and the second row was lengthened.

The model was then reconstructed according to this idea, making the piling 12½ in. (125 ft.) instead of 8½ in. (85 ft.). Tests were then made in exactly the same manner as before, and the results obtained showed a very noticeable effect due to the increased length of sheet-piling, which bore out the theory as to effect of sheet-piling and its similarity to the partly closed valve.

Fig. 11 shows typical results taken from the last series of tests, as in Table 3. Fig. 11 (*a*) shows a graphical record of the readings taken on the tubes. It will be noticed that the hydraulic grade line cuts the base of the dam well up stream from the toe. Fig. 11 (*b*) shows the hydraulic grade line of the lower set of tubes, where the distances from the up-stream toe of the dam to each tube were plotted horizontally, to show more correctly the hydraulic grade line of the water flowing through the gravel beneath the dam. Fig. 11 (*c*) shows the seepage, in cubic feet per second, per linear foot of the model.

Fig. 7 shows the tank for testing the model, under a full head. The water was colored red in order to show clearly in the photograph.

The down-stream section of the dam was constructed of the same material as the foundation, in order to provide adequate drainage and

for economy. It will be noted, from the plotting of the readings of the upper row of tubes, that there was no water in this section of the dam, except possibly that due to capillary action. This contributes a great deal to the stability of the dam as a whole.

It will be noted from Figs. 10 and 11, that the water traveling at great depths is not materially affected by the sheet-piling, at any particular point; but, throughout the whole distance under the dam, the general effect is obtained. This may be attributed to the extremely slow velocity of the water.

* Percolation, in cubic feet per second per linear foot of model.

† Readings for Tube *A* were excessive, due to breaking through the thin section of model dam over that tube.

Minus readings show that the pressure, as indicated by the tubes, did not reach the base of the dam.

Figs. 10 (*c*) and 11 (*c*) show the seepage water coming through under the dam. The results show that seepage water will follow the straight-line rule, after the soil is once filled with water and a sufficient head has been reached to overcome the friction. The rate of increase of flow, for each additional unit of head applied, varies for sands and gravels under different conditions, such as porosity of sand or gravel, character of voids, etc. As it would take a very extensive set of experiments to make any determinations in regard to the laws of seepage, the writer merely wishes to present the results so that others may use them.

In any dam, the correct place for a cut-off wall, under conditions such as these, namely, a pervious foundation, is at, or near, the up-

stream toe. However, in an earth dam, it must of necessity be placed nearer to the center, or axis, of the dam. For construction reasons, the sheet-piling in this dam was placed a short distance up stream from the center line, but, at the same time, it was sufficiently far back to prevent any water from seeping through the dam to the down-stream side of the piling in any appreciable quantities.

Conclusions.

Earth dams fail from four main causes, and the writer desires to show how structures of this type may be made safe.

One cause is from overtopping, due to high waves or a flood. This is provided against by designing an adequate spillway and providing sufficient free-board. This point has not been discussed in this paper, as it is governed by local and not general conditions. The concrete core-wall was designed to extend to the top of the embankment, which would prevent waves from cutting through.

A second cause of failure is by water seeping along a conduit placed in the built-up portion of the dam. In the present case, the outlet consists of a tunnel through the rock cliffs at one end of the dam, thus eliminating this cause of failure.

A third cause, and an unseen one, is burrowing animals. Where the down-stream section is loose rock this cannot happen, and it is much the same in loose gravel.

The fourth cause is the occurrence of springs, or boils, on the down-stream face of the dam, or near it, which in turn cause blow-outs and sloughing off of the bank. A solution of this problem was the main object of these experiments. Springs, or boils, are caused by not consuming all the head of water above the dam. From the tests described herein, it is seen that either an extreme length of base of the dam must be provided, or there must be sheet-pile cut-off walls of the proper length. Where the sand or gravel foundation is of very great depth, a short cut-off would not be as efficient as in a shallower foundation, but where models are constructed, results can be obtained which enable the engineer to make correct designs better than by any other method of study.

Finally, the writer wishes to state that he claims no new discovery, but has determined a type that has solved the problem under the conditions with which he was confronted. This type has been

built before, but has not been advanced together with reliable information from tests, etc. The study of the effect of the sheet-piling will undoubtedly be of value to the Profession. The application of the sieve analysis curves in combining the materials, for the purpose of determining the densest mass obtainable, has not been advanced before—as far as the writer knows—but its value as a time saver can easily be seen. Levees, canal banks, dikes, etc., may be studied in the same manner. Each design is a problem in itself, and the experiments described herein should not be misinterpreted, or applied too broadly.

DISCUSSION

Mr. Bligh.

W. G. BLIGH,* M. AM. SOC. C. E. (by letter).—This paper is of exceptional interest, as it deals with the first actual experiment made in many years with the object of ascertaining the value of the reduction in pressure or head caused by vertical obstructions such as curtain-walls or diaphragms of sheet-piling projecting below the base of a dam.

Any experiments with models, to be of authoritative value, must be on a reasonably large scale, and, further, the conditions should not deviate from those actually encountered in practice. In the present case, the scale of the model is considered too small, and might well have been 10 ft. to 1 in. However, the experiments in question were undertaken by private parties for a specific purpose, and the results obtained are sufficiently reliable for the aim in view. It is sincerely to be hoped that this good work may be continued, and this much discussed point finally disposed of in a convincing and indisputable manner. With regard to the second suggested condition, the experiment is all that could be wished, the relation between the head of water and the length of base provided in the model being the same as would be the case in the actual dam when constructed. This condition has not been observed in the paper by J. B. T. Colman, Assoc. M. Am. Soc. C. E., on "The Action of Water Under Dams",† where the disproportion between the head of water and the length of travel provided for the percolating undercurrent is unreal and, in a measure, must vitiate the authoritative value of the deductions obtained.

In the model dam, the base length was made dependent on actual experimental data obtained by filtration. This determined the net value of base length or travel of the percolating current requisite to neutralize entirely the head of water. It is quite evident that the length thus obtained must in many cases be a maximum value, whereas the minimum safe base length is the real criterion. Supposing the base to be shortened, the neutralization of the whole head would then still take place, but the velocity of the percolating undercurrent would be increased, as well as its ability to wash out and carry away particles of sand or gravel from under the dam and thus threaten piping action, which, in time, would cause undermining. This minimum length of travel suitable to any description of substratum could be obtained by actual experiment to which a factor of safety would necessarily be applied of, say, not less than 1.3. It is possible that, in certain cases, the base length thus deduced would nearly equal the maximum, but in nearly all instances it will be very much less. For

* Toronto, Ont., Canada.

† *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 421.

Mr. Bligh.

example, in the extreme case of a loose boulder river bed, the length requisite to neutralize completely a given head of water by filtration would be altogether impracticable; on the other hand, owing to the weight of the individual particles composing the foundation, a comparatively high velocity in the undercurrent would be admissible with a correspondingly reduced length of base. As far as the writer is aware, no comprehensive experiments have ever been undertaken to solve this matter in a really satisfactory manner.

The so-termed "percolation factors", first introduced some years ago by the writer, were deductions from actual failures of certain large river works, and although they are undoubtedly reliable for beds of pure sand, and have been accepted as such, still further definite experimental data would be most desirable.

This experiment demonstrates that the loss of head due to the vertical diaphragms is proportionally less in the rear than in the fore sheet-piling, and that, in neither case, is this neutralization in agreement with the so-termed "creep" theory. The author attributes the great difference in the effectiveness of the two lines of sheet-piling to the much greater depth of fore piling as well as to its location half way down the base of the dam, the assumption being that the obstruction of the deep curtain in the center of the base acts as a throttle valve to the percolating subcurrent at a position where the latter is well under way, thus causing a sudden loss of head. This view the writer deems to be correct, but applicable only to the quite abnormal conditions present in the experimental model. The depths given to the sheet-piling are far in excess of actual practice. That of the central line reaches to 125 ft. below the base of the dam, that is, to half the depth of the porous stratum; half the waterway is thus cut off, which must cause congestion. It is quite possible that this throttle-valve action may exercise a retroactive effect on the rear diaphragm, reducing its efficiency. However this may be, it is evident that the abnormal conditions existing in the model render the results obtained from the experiment of small practical value, and that the actual neutralizing effect of vertical curtain-walls remains still to be decided by further experiments made under normal conditions.

Mr. Colman, in the interesting discussion on his valuable paper previously mentioned, states that, in his opinion, sheet-piling is of no value in the reduction of head because it is not absolutely water-tight. This view is also held by irrigation engineers in India. In that country curtain-walls are made of oblong masonry under-sunk blocks, the narrow spaces between which are closed as well as practicable with concrete. Reliance, however, is not placed on these massive curtains with regard to their capability in the neutralization of uplift. In Egypt, cast-iron piles were used in the Assiut Barrage, and each joint was provided with a hollow space which was filled with cement grout.

Mr. Bligh.

It is believed, however, that the vertical length was omitted from consideration, owing to the lack of reliable data regarding their action. From these remarks, it will be evident that experimental data of a positive and exhaustive nature regarding this important subject would be a great boon to the Profession all over the world. Until such data are obtainable, it is thought that the theory of "creep", which even Philip à M. Parker,* M. Am. Soc. C. E., has termed "fascinating", should hold good as a fairly accurate and safe guide in design.

Some new developments have recently been made by the writer and published in a small work entitled, "Dams and Weirs", a copy of which has been presented to the Library of the Society.

In this the term "piezometric line" is used for the stepped line which forms the upper boundary of the area of uplift, thus distinguishing it from the hydraulic gradient, which latter is the ratio, $H : L$, L denoting the total length of travel, or creep, vertical as well as horizontal. Whatever value is assigned to vertical obstruction, it is clear that wherever it occurs a step down must result in the piezometric line and, further, as will now be shown, the latter will not necessarily be always parallel to the hydraulic gradient. Where there is no vertical curtain and no part of the superstructure is porous, the hydraulic gradient and piezometric lines will naturally coincide. A further development consists in the introduction of a filter bed of porous material, or the insertion of holes in the solid impervious floor or apron, which have the effect of stopping the uplift behind it by allowing the free exit of water. If solid material is prevented from passing out with the escaping water, all deleterious piping action is nullified; consequently, this porous length can be considered as effective as part of the line of travel of the percolating undercurrent. Thus, the direction of the piezometric line will be still further divorced from the sloping line, $\frac{H}{L}$, termed the hydraulic gradient. The introduction of a filter bed in the fore apron of the Hindia Barrage on the Euphrates was the first instance of this kind on a large scale. Another point of importance which may well be mentioned is the formation of a rear apron, impervious to water, behind a high dam, by the promotion of silt deposit by the river itself. This process can be facilitated by constructing the dam in stages, thus allowing time for the gradual deposit during several freshets. Many dams owe their safety to this complaisant action of natural forces, which otherwise, due to insufficient provision of enforced travel of the percolating undercurrent, would have failed. One further matter remains to be mentioned while there is opportunity for bringing it to notice: What is the effect, if any, of the imposition of weight on a porous foundation,

* "The Control of Water."

Mr. Bligh. subject to a head of water, in preventing or delaying its disintegration by piping?

The writer has checked the estimation of the loss of head due to vertical obstructions, according to the "creep" theory, and the results show the author's statements to be erroneous.

In Fig. 8, the length of travel is: horizontal, 745 ft., vertical $(2 \times 65 + 2 \times 85) = 300$ ft. The total value of L, then, is $745 + 300 = 1045$ ft. The hydraulic gradient will then be 1 in 10.45. The neutralization of head effected in the rear diaphragm would then be $\frac{2 \times 65}{10.45} = 12.4$ ft.; and that in the fore piling will be $\frac{2 \times 85}{10.45} = 16.2$ ft., as compared with the actual results, 5 and 21 ft., respectively, the discrepancy in the totals being only 2 ft. With regard to Fig. 9, the vertical component is $2 \times 125 = 250$ ft.; adding this to the horizontal, which is the same as before, that is, 745 ft., $L = 995$ ft., say, 1 000 ft., and the hydraulic gradient is 1 in 10. The loss of head due to the vertical diaphragm will then be $\frac{2 \times 125}{10} = 25$ ft. In Fig. 11, the loss of head appears to be about 20 ft. If the piezometric line, due to the theory of creep, were plotted over the experimental one, the differences would be apparent to the eye. This places the theory in a much better position than was previously apparent, and also somewhat discounts the special pleading in its favor made under a partial misapprehension of the facts. However, the experiment being made under abnormal conditions, the results cannot be accepted as convincing.

Mr. Oakes. J. C. OAKES,* M. AM. SOC. C. E. (by letter).—The application of the term "hardpan" to an uncemented material is unfortunate, as the meaning of the word in engineering literature is limited to materials hard to excavate, and more or less cemented by clay, carbonate of lime, oxide of iron, or other binding material.

In the last paragraph of "General Conditions" the stratum of so-called hardpan is referred to as "the impervious stratum." Later, in the experiments to determine the hydraulic gradient of the combined material, it is proved that this material is not impervious, but that it is readily saturated; for the porosity of the combined material is determined by that of the finer material, and, referring to the experiment to determine the gradient of the combined material, the author states:

"In the morning of the second day, fully 80% of the water was still on the surface, and at the end of 47 hours both tubes were filled with water, although the valve at the base had been closed for the entire period."

* Major, Corps of Engrs., U. S. A., Philadelphia, Pa.

Mr. Oakes.

It is apparent, therefore, that even though the valve at the bottom remained closed, the water drove out the air and fully saturated the material in the tank, as there existed no difference in head in the two tubes at the end of the test period.

The author states that it was found impossible to determine the exact hydraulic gradient of this combined material, because in another test "no water appeared in either of the tubes shortly after the valve was opened." It is evident that a sufficient length of time was not allowed to elapse, else the water would have appeared in the tubes, as proved by the saturation of this material just mentioned. He then assumes that the hydraulic gradient of the combined material "was not greater than 1:1, although it was evidently much steeper."

The writer supposes the author to mean that the slope of the gradient was not less than 1:1, although the tests apparently proved nothing. The slope of the hydraulic gradient in earthen dams is not generally as steep as 1:1, and in fact is seldom steeper than 35:100. It would seem, therefore, that careful and thorough tests should have been made before assuming 1:1 as the proper slope of the gradient for the material in question.

Furthermore, the assumption is made that, by using the combined materials in the up-stream section to secure water-tightness, and avoid transmission of water pressure through that section in any great amount, the hydraulic gradient can be made to begin at or near the up-stream toe of the dam. This is a dangerous assumption, as the material will become saturated, and some seepage will take place. Even if the fine material had been found, experimentally, to be practically impervious, it was not safe to assume that the coarse and fine materials could be mixed on a large scale in such manner that there would be, throughout the whole length of the dam, no points where the mixture would be imperfect, and where water might not seep through the combined material with greater or less facility.

Those who have had experience with filter beds, or have studied their action, know that care must be taken in placing the filter bed materials so that a uniform density will result. Whenever variation occurs, the water readily finds the paths of least resistance, and soon forms small channels through which it escapes. These channels gradually become larger, until the efficiency of the filter is destroyed. Lack of uniformity of the mixture of the materials under discussion will undoubtedly cause similar action, and, with material as fine as that described, a small quantity of seepage may cause piping, or the carrying away of the material, and the destruction of a portion of the up-stream section of the dam. Again, in Table 1, showing mechanical and chemical analyses, it is stated that 52% of the fine material is insoluble. If then, 48% of this earth is soluble, seepage

Mr. Oakes.

through it may be assisted very materially by the dissolving of the soluble parts.

With reference to the upper line of sheeting used under the first model dam, the author states: "* * * the loss of head is very small and not in proportion to the length of the sheet-piling." He does not explain why this upper row of sheeting did not accomplish as much in proportion to its length as the lower row, but, relying on what seems to be insufficient data obtained from a very small model, he abandons the upper row of piles and evolves a theory, which he claims explains the results obtained, but which, the writer thinks, does not explain those results satisfactorily. This theory is:

"* * * the sheet-piling cut-off was greatly similar in its effect to a partly closed valve, wherein the water is retarded and shows a higher pressure head just above the cut-off and a lower one just below."

He states that this theory wholly explains the ineffectiveness of the upper row of sheet-piling as a cut-off, but the writer does not see why, if the theory is correct, the upper sheeting should not also have acted as a partly closed valve. In other words, why does not the theory apply to one line of sheeting as well as to the other? It is a generally accepted principle of design that, where the apron is water-tight, the row of sheeting to be most effective must be at the up-stream edge. If the up-stream section of the dam, composed of the mixed materials, had been impervious, and the sheeting water-tight, it seems to the writer that the greatest effect, in proportion to length, would have been obtained by the upper row of sheeting. The author appears to recognize this faintly, for, on page 22, he states:

"In any dam, the correct place for a cut-off wall, under conditions such as these, namely, a pervious foundation, is at, or near the up-stream toe."

This statement is certainly correct when the dam is impervious, but it is not correct in case of a pervious dam or apron. It seems to the writer that the inefficiency of the upper row of sheeting can be readily explained, either by its lack of water-tightness, or by seepage through the material of the dam, between the pool and some point or points of the foundation down stream from the line of sheeting. Owing to the short period of time during which the experiment was carried on, the material above the second line of sheeting, being much thicker, did not become thoroughly saturated, seepage did not proceed directly from the pool through the material of the dam to a point down stream from the second row of piling, and consequently this row of piling did accomplish what was to be expected of it.

Although nothing is said about the length of time to which the model was subjected to the various heads of water, it is noted that, on each

of the days that the work was carried on, from four to eight experiments were made. In one case five experiments were made in the afternoon, so that it is very evident that a very short period of time was allowed for each experiment. With the material as fine as that described, complete saturation near the core-wall could not have been expected in such short time, but if, in each experiment, the head had been maintaned for a number of days, complete saturation would have taken place, and it would then have been found that the lower line of sheeting was also inefficient. Mr. Oakes.

Nothing is stated in the paper as to the percentage of voids in the coarser material, but the impression is given that water passed through this material very freely. If, then, after a time, the material in the upper section of the dam becomes thoroughly saturated, the writer does not see what is to prevent the carrying away of the fine material of the dam section through the coarser material of the foundation, thereby causing ultimate failure of the dam. He can see no advantage whatever in placing the line of sheeting as shown in Fig. 9. If the material forming the upper section of the dam is impervious, then the line of sheeting should be near the up-stream edge. If the material is not impervious, then it should be under the core-wall and connected therewith to form an impervious sheeting from crest of dam to foot of piles.

Fig. 8 indicates that the proposed dam is to withstand a depth of water of 100 ft., and Fig. 9 shows the design with a base approximately 700 ft. wide. For 100 ft. of this width the dam section is from 10 to 15 ft. thick. As the core-wall and sheet-piling do not necessarily increase the line of percolation, the percolation factor, or ratio of length of line of percolation to head, is approximately 7, which is much too small, if the writer understands the nature of the materials of foundation and dam section. Furthermore, it may be possible for seepage to take place along lines at 45° with the vertical and meeting at the foot of the core-wall, in which case this factor becomes about 2¼. This possibility is increased because the core-wall will tend to concentrate the seepage at its foot, and such seepage will escape under the wall and upward through the down-stream section, probably at an angle of approximately 45 degrees.

According to the best authorities, these factors are too low. Among these authorities may be cited Mr. W. G. Bligh, whose experience and theories are dismissed by the author with the statement:

"This theory gives structures of ample dimensions, as has been shown by practice, but was found to be incorrect, after due experimenting, as will be noted later."

If the author means that the experiments that he describes in this paper prove the falsity of Mr. Bligh's theory, the writer must dis-

Mr. Oakes.

agree with him, as, in his opinion, the model was too small, the experiments too few, and too little time was devoted to each experiment to warrant any such broad statement. It seems to the writer that erroneous conclusions, or at least unwarranted conclusions, were drawn by the author. It seems very doubtful whether results obtained with such a small model may be considered to hold for heads 120 times as great as those used in the experiments. In writing about the failure of a dam on sand foundations, and giving his opinion on the values of required percolation factors, Mr. Bligh has sounded a warning which exactly covers this case, as follows:

"The proper value of this factor is found, not by artificial experiments on a small scale, but by undisputable statistics which bear on the capacity of the various pervious materials which may compose a river bed to resist the undermining influence of the pressure of the water upheld."

A remarkable statement occurs on page 15, as follows:

"The long up-stream slope was given in order to allow the downward pressure of the water over the up-stream section to have a balancing effect on the upward pressure beneath the dam, as blow-outs would be improbable in this portion of the dam."

If the writer understands this sentence correctly, the author seems to feel that, although improbable, blow-outs may occur in the bottom of the reservoir, and he extends the dam up stream to prevent this by providing something for the down-stream pressure of the water to act on.

Although the author, under "Conclusions", has mentioned the principal causes of failure of earthen dams, he makes a number of statements in the last two paragraphs that do not seem to follow necessarily from the experiments described in this paper. Although possibly true, he has certainly not proved that:

"Where the sand or gravel foundation is of very great depth, a short cut-off would not be as efficient as in a shallower foundation, * * *."

Nor has he proved by his design that:

"* * * where models are constructed, results can be obtained which enable the engineer to make correct designs better than by any other method of study."

It appears to the writer that the use of a very small model, and the lack of certain precautions, such as allowing sufficient time in each experiment for the material to be thoroughly saturated, and the assumption that the material is impervious, or practically so, where it is very evidently not so, has led the author to arrive at erroneous conclusions, and to design a dam, which, if constructed as designed, is likely to fail.

Mr. Oakes.

The writer has had occasion to be deeply interested in the subject of dams on sand foundations, and has found no example of a dam on a pervious foundation constructed with a cross-section approaching in boldness that designed by the author. It will be very interesting, indeed, to know whether the dam has been constructed as designed, and, if so, to learn at a later date how it fulfills its purpose.

There is a statement at the end of the paper to which the writer is willing to subscribe in its entirety, as follows:

"Each design is a problem in itself, and the experiments described herein should not be misinterpreted, or applied too broadly."

Mr. Grunsky.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—The question of the effect of water-tight sheet-piling which does not extend entirely through a layer of pervious material, on the hydraulic gradient in that layer, is one of vital importance in many cases where either a dam must be built on a pervious foundation or not built at all. Every contribution toward the solution of this problem should be welcomed by the Profession. The writer suggests one which should be tried out:

Let D represent the depth of the gravel bed, in feet.

Let d represent the depth of the sheet-piling, in feet.

Let s represent the fall, in unity, of the hydraulic grade line for those portions of the gravel bed not affected by the sheet-piling. This is the gradient that will cause a flow in the gravel equal in quantity to the leakage under the dam.

Let S represent the fall in unity required to create the velocity with which the water flows under the sheeting through a section of gravel from B to C, Fig. 12, being a layer with a thickness of $D - d$ feet in which the water is assumed to flow horizontally.

Let h represent the reduction of hydrostatic pressure due to the sheet-piling, expressed in feet.

The velocity of the water in the gravel is proportional to the hydraulic gradient. Therefore,

$$S = \frac{D}{D - d}\, s \qquad (1)$$

The velocity at which water moves through the gravel toward the gravel-filled space, O-B, under the sheet-piling, Fig. 12, decreases with the distance from O-B. Uniformity of velocity at uniform distance from O-B may be assumed. Up stream from the sheet-piling, therefore, the hydraulic gradient should be practically constant at each point of each of the full concentric lines shown in the diagram, and there should be a gradual increase of the gradient from s at the outermost line passing through A, C, and D, to the gradient, S, at all points on the line, O-B. Down stream from the sheet-piling,

* San Francisco, Cal.

Mr. Grunsky.

on the other hand, there should be a gradual decrease of the hydraulic gradient from S at the line, O-B, to s at the outermost of the concentric lines passing through A, C', and D'.

The change in the gradient from s to S, up stream from the line of sheeting, and from S to s, down stream from the same line, is practically proportional to the distance from O-B, because the increase of the area of the gravel through which the water must pass is proportional or nearly so to this distance, and velocity and therefore velocity head in a gravel bed are inversely proportional to cross-sectional areas.

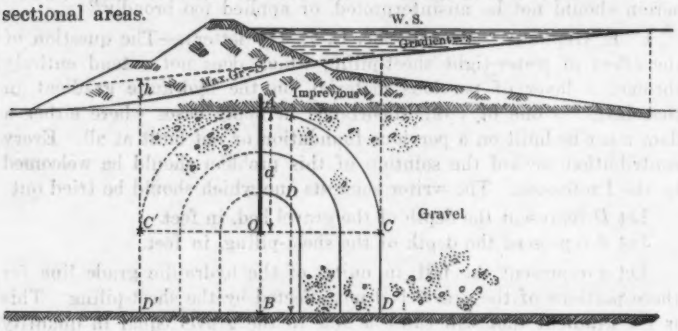

FIG. 12.

It follows that the total fall of the hydraulic grade line throughout the distance, C-C', will be

$$\frac{S+s}{2} \times (C\text{-}C').$$

But $C\text{-}C' = 2\,(A\text{-}O) = 2\,d$.

The total fall of the hydraulic grade line in the distance, $C\text{-}C' = D\text{-}D'$, is, therefore,

$$\frac{S+s}{2}\,(2\,d), \text{ or } d\left(\frac{S+s}{2}\right).$$

The fall of the grade line in the same distance, if there were no sheeting, would be $2\,d\,s$.

Consequently:

$$h = d\,(S+s) - 2\,d\,s \quad \ldots\ldots(2)$$

$$h = d\,(S-s) \quad \ldots\ldots(3)$$

Substituting the value of S from Equation (1),

$$h = d\left(\frac{D}{D-d}\,S - s\right) \quad \ldots\ldots(4)$$

$$h = \frac{d^2\,s}{D-d} \quad \ldots\ldots(5)$$

or,
$$h = \frac{d\,s}{\frac{D}{d} - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Mr. Grunsky.

When there is no sheeting, $d = 0$ and $h = 0$. When the sheeting extends to bed-rock, then $s = 0$, $d = D$, and h is indeterminate; the flow is completely checked. This also appears from Equation (1), which makes $S = \infty$. The fall in unity at the sheeting is infinity, and the hydraulic gradient comes to a full stop at the line of the sheeting.

Equation (5), applied to the F. C. Horn model, for the particular case when $s = 1:9$, indicates the following for 85-ft. sheeting:

For $D = 240$ ft.
and $d = 85$
and $s = 1:9$

$$h = \frac{85 \times 85}{155} \times \frac{1}{9} = 5.2 \text{ ft.}$$

For 40-ft. sheeting $d = 40$,

and
$$h = \frac{40 \times 40}{200} \times \frac{1}{9} = 0.9 \text{ ft.}$$

For 125-ft. sheeting, the loss of head would be 15 ft.

These results, it is believed, are fairly dependable. The hypothesis on which they are based is certainly more reasonable than the "creep theory" for which the writer has found no theoretical justification.

It will be noted that the examples here given apply only to the particular cases in which $s = 1:9$, that is, $s = 0.11$. To make comparisons with the experimental results obtained with the model, the first determination should be of the value of s, which will vary for each length of sheeting. The effect of the sheeting expressed by the total drop of the gradient is proportional to s, which is a variable.

The slope of the hydraulic gradient, or value of s, to be used in the equation for h can be ascertained for a model from the volume of flow through the gravel, by making experiments with varying quantities of water, and a corresponding variation of head, before the sheeting is placed in position. For this experiment, however, the gravel should be covered with an impervious material, so that the entire discharge must pass through the gravel. After the sheeting has been placed and the flow of water under it has been ascertained, this volume will determine, from the results of the preceding experiments, the proper value of s.

There is now to be considered the problem of determining the effect of sheet-piling when the value of s which will obtain after the sheet-piling is in place is not known.

Mr. Grunsky.

Without any sheeting under a dam of impervious material the hydraulic grade line may have any of the positions, *a*, *b*, or *c*, Fig. 13. When in the position indicated by the line, *a*, the outfall of the water into a channel or other receiver below the dam takes place with a more or less abrupt release of pressure, the dam is in danger. When the hydraulic grade line is in the position, *c*, the flow in the gravel under the dam is so small that water will not appear at the down-stream toe of the dam. When in the position, *b*, all water appearing at the down-stream toe will be under no pressure at the ground's surface, and the water passing under the dam ceases to be a menace.

FIG. 13.

Let it be assumed that, in the case of the finished structure, which has the benefit of sheet-piling, the hydraulic grade line passes through the down-stream toe, so that the average gradient of the line is $H \div L$. For this particular case, the effect of the sheet-piling can be estimated as follows:

The average gradient throughout a distance of about d feet on either side of the sheeting, as already shown, will be $\frac{S+s}{2}$.

The value of H will be

$$H = (L - 2\,d)\,s + h \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

$$H = (L - 2\,d)\,s + \frac{d^2\,s}{D - d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

from which

$$s = \frac{H}{L - 2\,d + \frac{d^2}{D - d}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

$$s = \frac{H\,(D - d)}{L\,(D - d) - d\,(2\,D - 3\,d)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

This value of s substituted in Equation (5) will make

$$h = \frac{d^2}{D - d} \times \frac{H\,(D - d)}{L\,(D - d) - d\,(2\,D - 3\,d)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

$$h = \frac{d^2\,H}{L\,(D - d) - d\,(2\,D - 3\,d)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Mr. Grunsky.

This expression for h represents the effect of the sheet-piling when the hydraulic grade line has been brought into the position, b, Fig. 13. In the case of earth dams, it will represent the benefit, expressed in head, which may be expected from the sheet-piling under a dam at the safety margin, and therefore the maximum benefit that may be hoped for from the use of sheeting.

The experiments made with the model are not described in the paper so that they enable one to test the equation by the tabulated experimental results. The low heads recorded for the points, H to K, indicate that the water was allowed to flow out of the drain cock. This would cause the gravel bed to act as a filter, and would produce a condition at variance with that which prevails at the dam site, where a free escape of water at, but not below, the level of the stream bed may be assumed. It is possible that the readings on the upper line of tubes and on the lower were not simultaneous, but, if this is the case, this should have been explained in the paper.

Mr. Pease.

H. T. Pease,* Assoc. M. Am. Soc. C. E.† (by letter).—This paper is an interesting example of the method expressed by the phrase *reductio ad absurdum*. It shows how far a line of reasoning may be carried beyond a logical limit.

No engineer would think of designing a bridge 100 ft. long using a test of a bridge 10 in. long as a basis for the design; especially would he consider the proceeding irrational if the conditions under which the model was tested were different from those actually to be met by the design. Mr. Hays' procedure is analogous to such a case. He has built a very large edifice on a very narrow base, a pyramid standing on its apex. Designing a dam 100 ft. high on the result of the tests of a model 10 in. high is a good deal like designing an ocean liner on the lines of a canoe.

The author's design would undoubtedly prove safe for a dam several feet in height, but that it would prove safe for more than 100 ft. of height is improbable; certainly, he does not prove his case. In a dam 10 in. high the effects of capillarity and viscosity of the water would be largely felt. In fact, they would undoubtedly comprise a large percentage of the total forces acting in this case. Such, however, would not be the case with the 100-ft. dam. These forces here would be negligible.

The final design shown in Fig. 9 indicates a slope of 2:1 on the up-stream face and a slope of 1½:1 on the down-stream face to a depth of 60 ft. Considering the nature of the material, as it is described in the paper, in fact, considering almost any material of which an earth dam might be constructed, this should be regarded

* Deer Park, Wash.

† Now M. Am. Soc. C. E.

Mr. Pease.

as an unsafe section for a dam of this height. A slope at least lighter than 1½: 1 should be used for the down-stream face.

The core-wall shown reaching to the top of the dam, in fact, the core-wall in any earth dam, is in most cases a "delusion and a snare". If the material of the up-stream portion is tight enough to hold water, the core-wall is unnecessary; whereas, if it is not tight enough to hold water, the up-stream portion serves no purpose whatever, except as a support for the core-wall when the dam is empty. Moreover, in such a case the pressure of the entire head, supplemented in many instances by an added weight of earth in a semi-fluid state, is brought to bear on the section at the core-wall. To say the least, such a stress would be hard on a thin wall such as is shown in the diagram, because the material supporting it is not rigid.

The up-stream toe would seem to be drawn out to too thin a section. If the material composing it is at all pervious, what is to prevent the finer particles from being carried down into the coarse substratum until this toe becomes as pervious as the ground beneath?

The author states that he has proved the "line of creep" theory incorrect, "after due experimenting". His experiments consist of the test of a model constructed on a very small scale, but of the exact proportions of the actual dam. Every detail but one is thus proportioned; while he was at it he should have reduced the sizes of the grains of the material of which the model was composed to the same scale, *i. e.*, 1: 120. A length of 24 in. of the natural sand and gravel placed under the model represents the 240 ft. of the same material which will be found at the dam site, and in this sheet-piling is placed reaching to within 11½ in. of the floor of the water-tight box in which the model is built. This is to represent piling which will be driven to a depth of 125 ft. below the base of the dam or within a distance of 115 ft. of an assumed rock surface below. That the actual subsurface conditions are thus duplicated in the model is hard to believe.

After making some tests for loss of head, the author concludes that the sheet-piling reaching to within 11½ in. of the floor of the box acts as a partly closed valve. There would appear to be an element of truth in his contention—in this case.

The conclusions to be drawn from the paper are:

That the author has shown a commendable enthusiasm and an attention to detail often lacking in such an investigation, but that he has over-estimated the usefulness of the data collected;

That the test conditions do not duplicate the actual conditions to be encountered; and

That the safety of his design is open to suspicion.

Mr. Elliott.

MALCOLM ELLIOTT,* ASSOC. M. AM. SOC. C. E.† (by letter).—The author of this interesting paper deserves credit and the thanks of engineers for efforts to throw light on a subject about which little is known, and for making his results and conclusions available to others. In commenting on this series of experiments, the writer wishes to disclaim any intention of merely picking flaws. What appear to be inconsistencies and errors may be due to misunderstandings which should be cleared up by other discussions.

The problem of determining the upward pressure on the base of a dam built on a pervious foundation may be likened to that of determining the lateral pressure of earth on the back of a retaining wall. No general theory of earth pressures will take care of all possible conditions as to cohesion and friction; neither will any general formula represent truly all possible degrees of porosity and permeability in the case of upward pressure on a dam. Nevertheless, for earth pressures, we are content to go on using the Rankine formula, well knowing that it does not accurately represent the true pressures, but using it because it gives practical values sufficiently near the truth for safety in design, when a reasonable margin of safety is provided. In like manner, the so-called "line of creep" theory may not accurately determine the upward pressures at the base of a dam, but it can be depended on as a generally safe rule for design.

The author recognizes that his results are not generally applicable; in his closing words he says that each design is a problem in itself, and that the experiments should not be applied too broadly. He might have added that his results could be used only for the dam which he was designing, and even then with extreme caution and proper allowances because of the small scale on which the experiments were made.

In using a model for any kind of a demonstration, it is desirable, of course, to reproduce, as faithfully as possible, the actual structure for which the strength or behavior is to be determined. This ideal cannot be attained in constructing models of dams on such a small scale as that used by the author.

In his model, the dam and sheet-piles are very much reduced in scale, though the soil particles are of the same size as those used in the full-scale dam, and the water is of the same degree of fluidity. The interstices in the sand, where it is in contact with the sheet-piles, are much larger, in proportion to the length of the piles, than they are in the actual dam. If the soil were reduced to the same scale as the dam and sheet-piles used in this series of experiments, it would be an impalpable powder; or, looking at it in another way, if the soil particles used in the model were enlarged so as to have the same relation in size to the actual dam as they have to the model dam, the

* Louisville, Ky.

† Now M. Am. Soc. C. E.

Mr. Elliott.

underlying material (Curve *A*, Plate IV) would be a mass of stones and boulders, 90% of which would be composed of pieces more than 2 in. in diameter, 80% would be stones more than 12 in. in diameter, and the largest "particles" would be boulders 10 ft. in diameter.

The tendency of the water to "creep" along the surface of the sheet-piles would possibly be greater in the actual dam than in the model, because of this difference in the size of the particles and their interstices when compared with the length of the sheet-piling. This seems to be substantiated by the greater proportionate loss of head at the second or longer row of sheet-piling. Here the measured loss of head for a 100-ft. head was from 19 to 21 ft., and the computed loss of head, according to the "line of creep" theory, with the hydraulic gradient of 1:9, would be *18.9 ft. From the very small loss of head at the first or shorter row of sheet-piling, the author deduces that this piling is of little value; and, in his second model, he eliminates it and adds to the length of the second row. The writer believes that if the author had used a model on a larger scale, or if he had increased the length of the up-stream row of piles in the model which he used, the loss of head due to the piles would have been more nearly in accord with that computed with the "line of creep" theory.

The small loss of head at the up-stream piles might also be explained in part by leakage through the apron on the up-stream slope of the dam. If, as is claimed by the author, this covering were impermeable, the logical place for the single row of sheet-piling would be in the up-stream trench, instead of the down-stream trench, and the concrete core-wall would be superfluous. Even a small leakage through this up-stream apron over the top of the upper row of piling would raise the hydraulic grade line down stream from the piles, thus apparently reducing the loss of head due to the piles. In his paragraph immediately preceding his conclusions, the author recognizes the possibility of leakage over the tops of the piles, when he says the piling was placed "sufficiently far back to prevent any water from seeping through the dam to the down-stream side of the piling", yet he does not attribute to this possibility the apparent failure of the "line of creep" theory at the upper row of piles.

One of the striking characteristics of the author's experiments is the apparently large loss of head where the water enters the sand. Thus, if the curve for Experiment 9, Fig. 10 (*a*), is extended to the toe of the dam on the same slope as between Tubes *B* and *C*, it appears that there will be a loss of head at entry of about 5½ in., out of a total head of 10 in. In giving his results in feet (the actual readings multiplied by 120), the author would apparently have us believe that

* Not 9.4 ft., as stated by the author. This is the loss of head on only one side of the sheet-piling.

the values he gives would approximate those to be expected with the full-scale dam, and that the loss of head at entry would be about 55 ft., out of a total head of 100 ft. If this were true we would have a surprising departure from hitherto accepted theories, which have been to the effect that the entry head, though appreciable, is not generally a large proportion of the total head. Mr. Elliott.

It is seen immediately, however, that accepted theories as to the amount of the entry head are not destroyed by the results of these experiments. The loss of head at entry is more nearly an absolute than a relative quantity; it does not vary with the total head, but with the velocity head. The velocity head with the actual dam will certainly not be 120 times that with the model dam; therefore the loss at entry will be relatively much smaller than with the model dam, leaving a much larger proportion of the total head to be overcome by friction, and thereby changing materially the slope of the hydraulic grade line.

Yet, if we should accept these experiments as conclusive, even with the limited applicability which the author claims for them, they would indicate a loss of head at entry, in the actual dam, of 55 ft., though, as a fact, it will be nearer 5½ in.

This difference between the model and the actual conditions is one of the fundamental reasons why the solution of this problem should not be attempted on such a small scale. The model should be of such size, compared with the actual structure, as to make negligible the error introduced by assuming that the loss of head at entry is proportional to the total head.

The departure of the author's results from those obtained by the "line of creep" rule may be explained largely by the relatively great loss of head at entry which is due to the small scale on which the experiments were made. With experiments on a larger scale, or under actual conditions, the loss at entry is insignificant, compared with the total head, so small, in fact, that it is entirely neglected in the "line of creep" theory as ordinarily applied.

The writer confesses not being able to understand the author's reference to the "hydraulic gradient of the underlying material" which he assumes to be 1:9 throughout. Apparently, he determined this by his preliminary experiments with the circular tank, and then for his trial design assumed that a certain down-stream slope of the dam would be necessary to "hold up the 100-ft. head". As the writer understands experiments of this kind, the purpose should be to determine what hydraulic gradient is required in order to reduce the velocity of the percolating water to such an extent that it will no longer have the power to transport the particles composing the medium through which it percolates. If the circular tank experiments gave

Mr. Elliott.

any information on this point, the author has not stated it in his paper. Clearly, the "hydraulic gradient of the material" could have been varied at will, either by increasing the head or the area of the outlet at the bottom of the tank, without in any way changing the character of the filling.

The author then assumes in Fig. 8 that the hydraulic gradient under the dam, according to the "line of creep" theory, will be 1:9, notwithstanding that this assumption makes the hydraulic grade line intersect the base of the dam well within the toe. The computed hydraulic grade line should intersect the base at the down-stream toe, to be consistent with the "line of creep" theory which the author wished to represent for comparison with the actual tube readings. According to the "line of creep" theory, and the dimensions adopted for the dam, the hydraulic gradient for a 100-ft. head should have been about 1:10.5 instead of 1:9.

Notwithstanding the foregoing inconsistencies, the author seems to have arrived at a generally safe and economical design for the dam which he had under consideration. Placing the relatively impermeable material on the up-stream face should result in making the hydraulic grade line begin near the toe instead of near the crest as it would have done if the dam had been built entirely of the material with which it was started.

The location of the piling near the center instead of near the up-stream toe is justified if the up-stream slope is not sufficiently tight to exclude the water. With a masonry or other water-tight dam, the piling, of course, should be near the toe.

The combination of local materials, in order to secure maximum density, is noteworthy, and the application of sieve analysis curves to this problem seems to be original. It would be interesting to know the construction methods by which the intimate mixture of the two materials was obtained.

Mr. Wegmann.

EDWARD WEGMANN,* M. AM. SOC. C. E.—The author is to be congratulated on the scientific manner in which he has worked up the results obtained with his model of an earth dam. Although the paper is interesting in this respect, the speaker does not think that any general conclusions, drawn from the results obtained with such a small model, will be applicable to the construction of a high earth dam.

In reference to Fig. 9, it is the speaker's opinion that, although in the experiment the water passed along the sheet-pile cut-off to its bottom and then rose again, in a high dam, built according to the model, the water would be very apt to take a short cut and pass over the top, instead of under the bottom, of the piling.

* New York City.

Mr. La Rue.

E. C. La Rue,* Assoc. M. Am. Soc. C. E. (by letter).—This paper will be of exceptional interest, for only meager data are available relating to the proper design of an earth dam having a gravel foundation. The partly completed dam, described by Mr. Hays, formed a part of an irrigation project on which the writer has prepared a water supply report. He has also examined the dam site, and is therefore specially interested in the paper.

In some parts of it the author has not made clear the procedure followed in his experimental work. For example, in determining the hydraulic gradient of the material used in the original dam and that to be used in the upper portion of the actual structure, the details of the methods are not made clear. The writer is in doubt as to the following points:

1.—When the readings were taken, was the quantity of water leaving the same as that entering the tank?

2.—Before the soil was placed in the tank, were tests made in order to determine the head required to force the water through the valve? If the coarse materials were tested to determine the hydraulic gradient, then, with the same quantity of water flowing into the empty tank as that used in the test, the head required to force this water through the valve could be determined. If, during such tests, it was found that the water level in the tank was above the intake to the lower glass tube, then the author's results are in error. During the tests, with the soil in the tank, the head required to force the water through the valve would be effective to a higher level in the tank. It is probable that the water level in the lower tube was not affected in the manner referred to, but the author has not made this point clear.

On page 5, in referring to the North Dike of the Wachusett Dam, Mr. Hays states:

"A flat hydraulic gradient, caused by the water in the reservoir seeping under the dam, called for a large quantity of material, in order to withstand the upward pressure under the down-stream portion of the dam."

In referring to the Gatun Dam, he states:

"A flat down-stream slope causes the percolating water to travel a long distance before a free opening is encountered, thus causing the upward pressure to be consumed by friction."

As the down-stream sections of these dams are constructed of pervious material, the water cannot exert an upward pressure on their bases. Probably the author means that the flat hydraulic gradient makes it necessary to construct the down-stream section of the dam with a flat slope in order to prevent the line of saturation from intersecting the down-stream face of the dam above the toe.

* Salt Lake City, Utah.

Mr. La Rue.

On page 15, in referring to the hydraulic gradient for the selected material to be used in the upper section of the actual structure, the author says: "From this it was assumed that the hydraulic gradient was not greater than 1:1, although it was evidently much steeper." This statement is not consistent. It would appear that he meant to say that the hydraulic gradient was not less than 1:1, and it was evidently much steeper.

On the same page, in referring to the model dam, the author says:

"The long up-stream slope was given in order to allow the downward pressure of the water over the up-stream section to have a balancing effect on the upward pressure beneath the dam, as blow-outs would be improbable in this portion of the dam."

Although the down-stream pressure of the water over the up-stream section does have a balancing effect on the upward pressure beneath the dam, this surely was not the reason for adopting a "long up-stream slope". The author assumes that the material in the up-stream section will be practically water-tight. It would appear, therefore, that the flat up-stream slope was adopted in order to force the hydraulic gradient to begin farther up stream.

The author concludes that, with 10 in. of water in the reservoir above the model dam, the head is entirely consumed before the water reaches the lower toe of the dam. Using Test No. 17, Table 3, the writer has drawn lines of equal pressure, and from these produced the lines representing approximately the direction of flow through the foundation of the model dam. The direction of flow was downward in that portion of the foundation above the sheet-piling. Below the sheet-piling the flow lines rose slightly and then appeared to turn in the direction of the drain valve, shown in Fig. 8. If the pressure had been observed at various points in the foundation below the lower toe, there is no doubt that it would have shown conclusively that the direction of flow was toward the drain valve. Mr. Hays has shown the hydraulic gradient for the material used in the foundation to be about 1:9. With a free escape for the water, as is provided by the drain, little, if any, pressure would be observed immediately above the drain valve. Extending the hydraulic gradient back from the drain valve with a slope of 1:9, it will be seen to intersect the line representing the base of the dam at a point 2 160 ft. above the drain, or 1 040 ft. up stream from the upper toe of the actual dam. All the pressure observations taken by the author must have been affected by the drain. Under these conditions, the water could not rise to the base of the dam near the lower toe. In the model, the author has imposed conditions which would not be reproduced in actual practice. If the dam is to operate under the same conditions as the model, then 360 ft. below the lower toe of the dam a trench, 240 ft. deep and 40 ft.

wide, must be constructed across the canyon. This trench must be filled with large stone, in order to provide a perfect drain. In the bottom of the trench, or at the 240-ft. level, there must be openings with sufficient capacity to carry off the water as it arrives. The water must then be conveyed to a reservoir of infinite capacity. In the model, the drain should be 216 in. from the lower toe, instead of 36 in., or it will affect the water pressure under the base of the dam. If the writer's contentions are correct, the results of the author's experiments are of little practical value. Mr. La Rue.

That the drain referred to has affected seriously the results of the experiments is indicated by the excessive seepage through the foundation of the model. In Test No. 17, Table 3, the seepage, per linear foot of the model, was 0.00222 cu. ft. per sec. The slope of the line of saturation in the model is assumed to be the same as that of the actual dam. The length of travel in the model is proportional to that of the actual dam. The head and all other dimensions in the model being proportional to those of the actual dam, the seepage through the latter, per linear foot, will be 120 times that through the model per linear foot. The length of the actual dam is to be 2 000 ft., and its left end will extend into a bank of gravel similar to that which is to compose the foundation. Considerable excavation will be necessary in order that the water-tight section of the dam can be carried well into this bank. It is assumed that the area exposed to water pressure will be equivalent to the area of 1 200 ft. of maximum section. The seepage through the actual dam, therefore, would be $120 \times 1\,200 \times 0.00222$, which equals 320 cu. ft. per sec.

Mr. Hays has not disproved the "line of creep" theory. In the first test, with the two rows of sheet-piling, he found a small loss of head at the upper row of piling. This, no doubt, was due to water passing through the upper section of the dam and entering the foundation both above and below the upper row of sheet-piling.

The pressure at *D*, Fig. 8, below the lower row of sheet-piling, was no doubt due to the water from the upper section of the dam entering the foundation between the piling and the cut-off wall. In fact, the drain would prevent the water from rising to *D* after passing below the lower row of sheet-piling. If Mr. Hays will place the drain 216 in. below the lower toe of the model dam, separate the upper section of the dam from the foundation, with a sheet of tin, and connect the tin with the cut-off wall and the two rows of sheet-piling with water-tight joints, then the hydraulic gradient will begin at the upper toe. Under these conditions, the effect of the two rows of sheet-piling can be determined, and undoubtedly the "line of creep" theory, somewhat modified, will prove to be correct. That is, instead of following down one side of the sheet-piling and up the other, thence along the base of

Mr. La Rue.

the dam to the second row of sheet-piling, etc., the water will follow down the upper side of the first row of sheet-piling and thence in the general direction of the lower end of the second row of sheet-piling.

Assuming that there were no other defects in the model, the writer believes the results of the tests to be unreliable for the following reasons:

1.—The model dam, being only 11 in. high, and subjected to a head of 10 in. of water, the entrance head and capillary action would, no doubt, affect the hydraulic gradient to such an extent that the pressure observations in the model would not indicate the action of the water in the final structure, where similar material will be subjected to a head 120 times greater than that on the model.

2.—The model dam was constructed of the same material as that to be used in the actual structure. It would seem that the material for the former should have been coarser than that to be used in the latter. The ratio between the coarseness of the materials in the two structures, which would result in the action of the water on the model being comparable to that on the actual dam, could perhaps be determined by extensive experiments.

The writer makes the following suggestions:

1.—That the author construct a model which will represent exactly the original dam as it was to have been built. It is probable that the results of tests on this model would show the structure to be safe, provided the model were constructed with the drain 36 in. below the lower toe. As a matter of fact, with a head of 24 ft. on the actual dam, the water passed freely through the partly completed structure.

2.—That the author could obtain more reliable information from a series of tests on models 1, 2, 4, 8, and 12 ft. in height, provided the drain shown in Fig. 8 were placed at a section 216 in. down stream from the lower toes of the respective dams. From the results of the experiments with each of these models, it is possible that some sort of a curve could be prepared which might be extended to show approximately the action of the water on the final structure under a head of 100 ft.

Conclusions.—

1.—The author has not stated clearly how each experiment was carried on. In some places it is necessary for the reader to assume that the experiment was conducted under certain imposed conditions.

2.—The model dam used by the author was too small to give reliable results.

3.—The pressure, at all points observed in the tests, was affected by the drain; therefore, the results of the experiments are of little practical value.

4.—The drain in the model should have been placed 216 in. below the lower toe, instead of 36 in. Mr. La Rue.

5.—The author has not disproved the "line of creep" theory.

6.—It would appear that too much dependence was placed on the impermeability of the material in the upper section of the dam.

7.—If the dam, as designed, were constructed to operate under the conditions imposed in the model, the flow under it would be about 320 cu. ft. per sec.

8.—It is the writer's opinion that the sheet-piling should be placed beneath the core-wall. If the core-wall in the partly completed dam is to be used, then the sheet-piling should be placed near the core-wall on the up-stream side. A water-tight connection should be made between the core-wall and the sheet-piling. The writer, being somewhat familiar with the conditions at the dam site, feels that, at best, there will be considerable seepage under the dam, and for this reason he would suggest that the slope of the down-stream face, below the 30-ft. berm, be made as flat as $3\frac{1}{2}:1$ or $4:1$. The proper slope for the down-stream face could no doubt be determined by extensive tests on a series of properly designed models of various heights.

GEORGE M. BACON,* M. AM. SOC. C. E. (by letter).—The main objection to drawing conclusions from these experiments seems to be the assumption that the foundation as composed for the model represents sub-surface conditions at the dam site, an assumption hardly correct. What part of the foundation in the model corresponds to the actual condition on the ground, which allowed sheet-piling to sink "as deep as 32 ft. with one or two blows from a 1 700-lb. hammer"? The mountain streams formed "great cones, or fans, of very porous material". Was this material duplicated in the model, and, if so, where? In an experiment of this kind, it is vital to duplicate the actual conditions which are the subject of investigation. No ingenuity of observation and recording can minimize the importance of this. There is practically nothing in the paper showing how the foundation in the model was formed, or indicating its similarity to actual conditions. Mr. Bacon.

The author's theoretical analyses are interesting, but, should they serve as a basis for the solution of the problem actually presented? If the premises are not correct, any deductions from experiment are not only of no value, but can easily be harmful as well as misleading.

H. A. PETTERSON,† ASSOC. M. AM. SOC. C. E. (by letter).—The writer is a great believer in experimental engineering, and realizes that much of the advance made in engineering knowledge is due to the researches of careful and ingenious experimenters. He cannot believe, however, that experiments made on models with a depth of Mr. Petterson.

* Salt Lake City, Utah.

† Tientsin, China.

Mr. Petterson.

water of only 10 in., will bring forth results of any great practical value in designing a dam to impound water 100 ft. and more in depth. Our knowledge of the underground flow of water is not as complete as it ought to be. This is true especially of underground flow as affected by cut-off walls penetrating only part way into the porous stratum.

The most reliable experiments, however, would be those made on existing dams and weirs built on porous foundations. There are many structures in different parts of the world on which experiments could be made, and these could follow essentially the methods developed by Mr. C. S. Slichter.* Until such experiments are made, the writer, for one, would advocate following present methods, a brief presentation of the underlying principles of which will be given.

The principles governing the design of an earth dam with impervious core-wall to impervious foundation need not be reviewed, as they are treated in any number of good textbooks. The problem of securing water-tightness in earth dams is essentially one of securing the maximum density of the material; and the laws governing this are known by the Engineering Profession, even though not universally applied. Strict adherence to these principles in earth dam construction involves extra cost, which is not always warranted by the results obtained.

This discussion, therefore, will be confined to the principles involved in the design of an earth dam on a porous foundation of such great depth that an impervious cut-off wall to an impervious stratum is financially impracticable. It will be assumed that the dam will be made relatively impervious, and safe against ordinary methods of failure. The principles to be elucidated are the securing of stability against the possible destructive effect of water flowing under the dam (not through it); also, as it is assumed that the dam is to impound water in a reservoir, the investigation of the quantity of water lost by percolation is important from an economic standpoint, though it may in no way affect the stability of the dam.

A rational design cannot be made without a comprehensive grasp of the laws governing the flow of underground water. A very brief summary of present knowledge on these laws will be given, for the purpose of calling attention to the incompleteness of that knowledge and to make clearer the writer's comments on certain of the author's statements.

Laws of Underground Flow.

Mr. Petterson.

Slichter's formula* is

$$Q = \frac{16\,272\,d^2}{k}\,\frac{h\,A}{L}\,[1 + 0.0187\,(t - 32)] \ldots\ldots\ldots (2)$$

Baldwin-Wiseman's formula† is

$$v = c_1\,c_2\,\frac{h}{L} \ldots\ldots\ldots (3)$$

In these formulas, c, c_1, c_2, and k, are coefficients. The values of c in Hazen's formula vary from 400 to 1 000. The values of k are tabulated by Slichter, and vary only with porosity. c_1, in Equation (3), is proportional to cd^2 and $\frac{d^2}{k}$ in Equations (1) and (2). c_2 corresponds to the temperature correction of Equations (1) and (2).

Q = discharge, in cubic feet per day, through the area, A;
A = area of cross-section, in square feet, normal to the line of flow;
h = difference of water surface, in feet, for two points distant L feet apart;
L = distance, in feet, measured in direction of line of flow;
d = effective size of sand grains, in millimeters, determined by mechanical analysis with sieves in Hazen's formula, and by the use of King's aspirator‡ in Slichter's formula;
v = velocity of percolation;
t = temperature of the water, in degrees, Fahrenheit.

These three equations all agree in several respects:

First.—The rate of flow increases with temperature.

Second.—The rate of flow increases with the first power of $\frac{h}{L}$, or, if h is constant, varies inversely with L.

Third.—The rate of flow varies with some power of the effective size of the sand grains.

By platting on logarithmic paper, a straight-line relation will be found to exist between Slichter's values of k and the porosity of the material. The same relation holds between porosity and the tabulated values of the transmission coefficient in Water Supply Paper

* U. S. Geological Survey, Water Supply Papers, Nos. 67 and 140; also, 19th Annual Report, U. S. Geol. Survey, Part II, 1899, p. 295.

† *Minutes of Proceedings*, Inst. C. E., Vol. CLXXXI, p. 15; also, Technical Paper No. 97, Govt. of India, 1902.

‡ For description of King's aspirator, see 15th Annual Report, Agricultural Experiment Station, Univ. of Wisconsin, 1898.

Mr. Petterson.

No. 140. It may be shown that Slichter's tabulated results may be expressed in the following form:

$$Q = \alpha\, p^{3.3}\, d^2\, \frac{h}{L}\, A\, T \qquad (4)$$

where p = porosity and T = temperature correction.

The effect of porosity is taken into account in all the equations. In Equation (1), the values of c vary with the uniformity coefficient, which is an indirect and approximate method of stating the effect of porosity. In Equation (3), the effect of porosity is introduced in the coefficient, c_1.

The writer believes that further experiments are required before a formula for underground flow will be developed which will be even approximately as accurate, for instance, as that for the flow of water in pipes and other conduits. Based on present knowledge, such a formula will have the general form:

$$Q = \alpha\, p^n\, d^m \left(\frac{h}{L}\right)^r A\, T \qquad (5)$$

Our present formulas are applicable to sands up to an effective size of 5 mm. Hazen specifically limits the range of his formula to sands of from 0.10 to 3 mm. effective size. The writer has introduced the exponent, r, in Equation (5) as necessary if the formula is to be applicable to all sizes of material. Thus, for large boulders, there is no doubt that r would approach a value of 0.5, as for flow in channels; and, for extremely fine material, such as silt and clay, r may become greater than unity.

Considering the equations for underground flow, we may, for convenience, combine the factors denoting effect of porosity, effective size, and temperature, and write an equation:

$$Q = \frac{K\, h\, A}{L}, \text{ or } p = \frac{K\, h}{L} \text{ for } A = \text{unity}.$$

The coefficient, K, may be taken as a constant for any given case, as for the gravel stratum under the dam described by the author. The head, h, is also fixed by the storage requirements. The only variables then are q and L. The hydraulic gradient equals $\frac{h}{L}$ and may have an infinite number of values, depending on the variable, L. There is, however, a definite relation between K and the character of the underground material.

The writer fails to grasp the author's meaning, when he refers to the hydraulic gradient of various gravels, as though there was only one possible hydraulic gradient for a given gravel. Thus, on page 7, the author states:

Mr. Petterson.

"Having determined the hydraulic gradient of the underground material, a trial design was made to find what dimensions would be necessary in a dam constructed wholly of this gravel."

Again, on page 8: "This combined material was then tested in the tank to determine the hydraulic gradient". On page 15, there is a reference in similar vein.

APPLICATION OF FORMULA FOR UNDERGROUND FLOW TO DESIGN OF DAM.

The underground flow may endanger the dam in two ways: (1) The velocity of flow may be sufficient to carry away with it the finer materials in the gravel, and the so-called "piping" action results. If this keeps on indefinitely, it is only a question of time until the underground stratum becomes so porous that all the water in the reservoir will readily escape, or the stratum will settle, and the superstructure will go down with it. (2) The upward water pressure under the base of the dam may be great enough to overcome the weight of the superincumbent earth, and so-called "blow-outs" occur.

(1) *Stability Against Piping.*—Considering the equation, $q = \frac{K h}{L}$, it is obvious, from what has been already stated, that q, or unit discharge, can only be reduced by increasing L. As the velocity is directly proportional to q, it, too, can only be decreased by increasing L, or, what amounts to the same thing, by increasing $\frac{L}{h}$.*

These coefficients are deduced from observations of existing structures, largely in India. They are not the results of experiments, but of compilations of data on structures which have proved to be safe. The writer cannot understand, then, why there is any lack of precedent in designing dams on porous sand foundations. The Laguna Weir is a notable example of a diversion dam founded on extremely fine silt. He agrees with the author as to the value, and even need, of further experiments, if this branch of engineering is to have a scientific basis, but cannot agree as to the value of experiments on models carrying only 10 in. of water.

A particular need for further investigation is the definite determination of the influence of cut-off walls, penetrating only part way through the porous stratum, in reducing the pressure head. According to the "line of creep" theory, this effect depends only on the depth of the barrier and the length of base, L; or, if L_c represents the depth of

*Tables of safe values of $\frac{L}{h}$, for material from fine silt to boulders, may be found in *Minutes of Proceedings*, Inst. C. E., Vol. CXCVII (1914), Paper No. 4004, by W. M. Griffith, or in a standard book like that of Thomas and Watt on "Improvement of Rivers".

Mr. Petterson.

penetration of this cut-off wall, and h_s the reduction of the pressure head, then

$$h_s = \frac{2\,L_s}{\frac{L}{h}}.$$

The writer believes that the value of h_s depends, not only on L_s and $\frac{L}{h}$, but also on the ratio of L_s to the total depth of the porous stratum. If S represents the depth of the porous stratum, and other symbols are as before, then $h_s = \frac{B\,h}{L}\left(\frac{L_s}{S}\right)^n$ is the form of expression which, the writer believes, presents the value of the lost head. B is a coefficient, and n an exponent.

A point of practical importance is the difficulty encountered in making these cut-off walls impervious. Sheet-piling is assumed by some engineers to be practically impervious, but experienced men point out the tendency for deep piles to spread, and mention the difficulty of preventing this tendency, even with interlocking steel piles. As the work cannot be inspected, there is always uncertainty as to the efficiency of sheet-piling.

(*2*) *Stability Against Upward Pressure Under the Base of Dam.*—The remedy against this method of failure is obvious. If y = the pressure head at any point, w = the weight per cubic foot of water, and m = the weight per cubic foot of the material in the dam; then wy is the intensity of pressure which is resisted by the weight of superincumbent earth. If z = the height of the dam at any point corresponding to y, then, for safety, mz should be greater than wy.

The foregoing discussion assumes that the material in the dam is impervious. If it is porous, the water plane will rise in the dam to heights corresponding to y. It is necessary, then, that z be greater than y. It is also necessary, of course, that the batter of the down-stream face of the dam be sufficiently flat to prevent sloughing of saturated material. The batter of the down-stream face will generally be sufficiently flat to ensure stability against sloughing, if it is designed in accordance with the requirements mentioned under "Stability Against Piping".

The writer believes that a more logical distribution of material is to make a flat down-stream face, with the up-stream face given the usual batter of earth dams, say 1 vertical to 3 horizontal. The material in the up-stream portion should be the most impervious. The reasons for this are well brought out by George L. Dillman,* M. Am. Soc.

* In his discussion on the paper by M. M. O'Shaughnessy, M. Am. Soc. C. E., entitled "Construction of the Morena Rock Fill Dam", *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 52.

C. E. Such great care need not be taken in the construction of the lower part of the dam, though the material should be considerably more resistant to flow than that of the underlying gravel stratum. In other words, the engineer should see to it that the dam is constructed so that greater resistance to flow is offered at all points by the dam than by the underlying gravel, but the most impervious material should be on the up-stream side. Mr. Petterson.

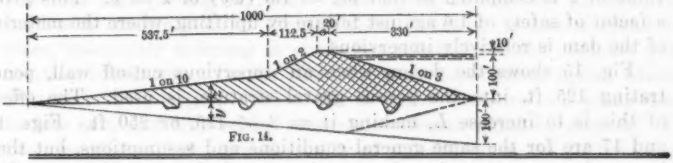

FIG. 14.

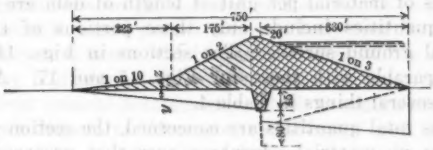

FIG. 15.

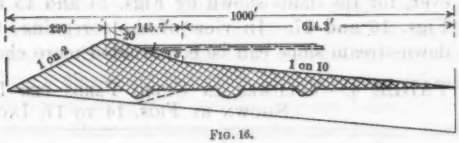

FIG. 16.

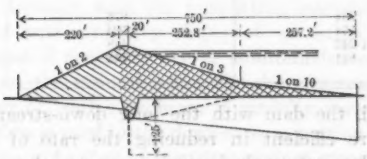

FIG. 17.

The author has reversed the usual method of distribution, in that he makes a steep down-stream face and extends the base up stream. The writer has prepared Figs. 14 to 17 in order to compare the usual design with that of the author. The total width of base in the author's design, as closely as can be determined from his Fig. 9, = 760 ft., and L_s, the depth of vertical barrier, = 125 ft. Then, by the usual

Mr. Petterson.

theory, $L = 760 + 2L_s = 1\,010$ ft. A value of $L = 1\,000$ corresponds to a value of $\frac{L}{h} = 10$, which would be about the value given, in the tables previously referred to, for the gravel described by the author.

Figs. 14 to 17 show four designs with a value of $L = 1\,000$. Fig. 14 shows a section without any vertical barrier constructed in the gravel. The value of m is taken at 100 and that of w at 62.5. The value of z is computed so that $mz = 1.6\ (wy)$ or $z = y$. This gives a factor of safety of 1.6 against failure by uplifting, where the material of the dam is relatively impervious.

Fig. 15 shows the design when an impervious cut-off wall, penetrating 125 ft. into the porous gravel stratum, is used. The effect of this is to increase L, making it $= 2 \times 125$, or 250 ft. Figs. 16 and 17 are for the same general conditions and assumptions, but they have a flat up-stream slope in accordance with the author's idea. The relative quantities of material per unit of length of dam are given in Table 4. The quantities include only those portions of the dams above the natural ground surface. The sections in Figs. 14 and 16 are directly comparable with those for Figs. 15 and 17. Attention may be called to several things in Table 4.

First, as far as total quantities are concerned, the section proposed by the writer has no material advantage over that proposed by the author. The quantity listed as up-stream material is far less, however, for the dams shown by Figs. 14 and 15 than for those shown by Figs. 16 and 17. In view of the foregoing, the dams with the long down-stream slope can be constructed more cheaply.

TABLE 4.—VOLUMES, IN CUBIC YARDS PER LINEAR FOOT, FOR DAMS SHOWN BY FIGS. 14 TO 17, INCLUSIVE.

Up stream.	Down stream.	Totals.
754	876	1 630
754	524	1 278
1 242	448	1 690
841	448	1 289

Second, the dam with the long down-stream slope is likely to be much more efficient in reducing the rate of percolation under the dam. Unless extremely impervious material is secured for the shallow portion of the up-stream section of dams like those of Figs. 16 and 17, it is very probable that there would be percolation downward through the dam, near the heel, adding to the underground flow. In other words, the value of $\frac{L}{h}$ for a dam of this type is less than for a dam of the type shown by Fig. 14, even with the same length of base and the same depth of sheet-piling, or other cut-off wall.

Mr. Henny.

D. C. HENNY,* M. AM. SOC. C. E. (by letter).—The design of a dam in a situation such as the author describes presents an interesting and difficult problem. In his conclusions he mentions several causes of earth dam failures, and states that his paper deals with one cause only, namely, springs or boils, which might produce piping under the base of the dam.

The usual percolating velocities are exceedingly low, far below the power of transporting material. The piping or blow-up phenomenon implies a combination of circumstances, relating to the material in place, essentially differing at particular points from the ordinary percolating conditions. In the case of clayey foundation, initial cracks may transmit a large portion of the available pressure to a point close to free exit, and may set up progressive erosion aided by arching. In the case of sand and gravel, strata of unusual openness to flow may be contiguous to layers of very fine sand. In very coarse material, the open spaces between pebbles and cobbles may be so great as to preclude true percolation and permit comparatively free flow and high velocity. The latter case is one which cannot be regarded as applying to foundations for high dams. The other cases are dependent on local deviations from general homogeneity, which for large areas can hardly ever be known definitely. Moreover, the effect of such deviations cannot be ascertained by experiments with selected samples of materials placed in tanks or boxes.

The experiments conducted by the author do not appear to have had for their object the determination of a maximum gradient which would be safe against piping, but rather the most economical form of dam which would produce a maximum reduction of the water gradient, thereby minimizing the piping danger as well as seepage losses.

It appears to the writer that, whatever may be the danger from piping, it must be judged by examination of test pits and experience with existing dams. Usually, with the foundation material which the author describes, and with ordinary slopes of an earth dam, such danger is not great, and if necessary can be counteracted economically by a gravel blanket on the ground below the down-stream toe. Nor need there be any fear of bank sloughing, if gravelly material similar to that in the foundation is used in the down-stream portion of the dam. The real problem seems to be that of insuring against excessive seepage losses such as would render the reservoir useless.

In describing the history of the reservoir, the author states that when the dam was completed to a height of 30 ft., it was subjected to a head of 25 ft., at which time water escaped in considerable quantity from the down-stream toe. Though the quantity of water escaping is not stated, it is evident that, if this is known or can be ascertained ap-

* Portland, Ore.

Mr. Henny.

proximately, a full-size experiment is at hand on which to base some judgment as to the seriousness of the problem.

A portion of this escaping water may have come through the dam proper. It is certain, however, that by far most of it passed through the dam foundation, which is described as being of a very porous nature and of unknown depth, roughly estimated at 240 ft.

If, at that stage of completion, the dam had a full width of base of approximately 500 ft., the water gradient producing this heavy seepage may have been 1 to 20, and a statement of the seepage per linear foot of dam would permit some judgment as to the practical admissibility, from the storage point of view, of such gradient for a full reservoir.

The author's determination of a safe gradient of 1 to 9 by vertical tank test is by no means conclusive. The essential feature, namely, the quantity of seepage with such gradient, is not stated. However, even if it were stated and were satisfactorily low, it is necessarily based on the use of samples of foundation material which, in the nature of the case, cannot represent any known sort of average of the deep masses of gravel, sand, cobbles, and boulders as they lie in place under the dam. Homogeneity cannot exist to any degree in material of greatly varying sizes deposited by successive floods of varying intensity.

Assuming, however, that the samples used in the author's tests are representative of the general foundation, the tests made in a rectangular box with a model of a dam with varying depths of tight cut-off show the quantity of seepage under full head. For the first model tested, this averaged approximately 0.0040 sec-ft., and, for the second model, 0.0025 sec-ft. per lin. ft. of model. The writer understands that these quantities refer to the flow measured in the experiments, on a scale of $\frac{1}{120}$ of full size. If this understanding is correct, then, so far as the experiment goes, the deduction may be made that, for similar material in the foundation, the seepage for a dam built on the basis of the second model would be 120×0.0025, or 0.3 sec-ft. per lin. ft. of dam.

The longitudinal section shows the dam to be 400 ft. in length across the general river bed and 1 600 ft. in length on the adjoining bench. No data are at hand as to rise of rock under this bench. It may be interesting, nevertheless, to inquire as to what the total seepage under the dam would be if the rock were to rise but slightly away from the river. In that case the average gradient and seepage per linear foot for the bench portion of the dam would approximate one-half that for the full height of the dam. On such assumptions, a seepage would result of $\left(400 + \frac{1\,600}{2}\right) \times 0.3 = 360$ sec-ft. This quantity of seepage is clearly inadmissible, and the writer deems it likely that

some of the foregoing assumptions may be known by the author to be erroneous. Mr. Henny.

Independent of the doubt regarding test samples being representative of material in place, there must be serious uncertainty as to the possibility of driving sheet-piling to a depth 80 ft. below the bottom of the cut-off trench, and as to the tightness of such sheet-piling when driven.

It will be noted that the final design of the dam as presented by the author shows an approximate gradient of 1 to 10 for full reservoir. This may be about twice the gradient which prevailed when there was 25 ft. of head against the present dam, at which time heavy seepage losses occurred.

A detailed study of the pressures as registered in the experimental box with the model of the dam reveals some marked inconsistencies, which, if the experimental results are to be made the basis for design, may require explanation. In considering this subject, the writer has confined himself to the use of experiments made under a full head of 10 in. representing 100 ft. on the scale of the experiment, and has selected for this purpose only those numbers, four in the first and three in the second series, for which pressures are recorded at all points.

Individual differences of flow and pressure are rather large, the maximum variations from the average being as follows:

	First series: Experiments 9, 14, 19, and 24.	Second series: Experiments 4, 8, and 12.
Flow	7%	20%
Pressure	20%	13%

In order to eliminate individual variations, whatever may be their cause, pressures and pressure drops are figured on the basis of average values and are listed for comparison in Table 5.

Table 5 shows the following rather surprising results as to pressure head destroyed by percolation: The pressure drop is greater from open water to *A*, from *B* to *C*, and from *D* to *E*, with smaller than with larger flow; the pressure drop is greater from *A* to *B* without sheet-piling, and with small flow than with sheet-piling and with large flow; the pressure drop is greater from *C* to *D*, in proportion to the flow, with shallow than with deep sheet-piling.

The drop from open water to the point, *A*, up stream from the points of cut-off, is 60% of the total head, in spite of the short distance of travel; so that the upper portion of the water gradient is steepest. The great loss of head at entrance appears to be inherent in experiments of this kind. It may well be doubted, however, whether such losses occur in the case of actual dams, where the area of entrance is very extensive, unless it is induced by silt deposits. Should no such

Mr. Henny.

loss with the actual dam be experienced, and should the pressure at *A* be 80 or 90% of the total head instead of 40%, the actual seepage losses may be double those deduced from the experiments.

In regard to the feature of the design consisting of a tight blanket up stream intended to lengthen the path of the water, the reasoning of the author is believed to be sound. The same method was advocated by the writer and was adopted in the case of the Grand River Diversion Dam built by the Reclamation Service near Grand Junction, Colo. The object in this case was the reduction both of uplift and of seepage. Fig. 18 shows a cross-section of this dam.

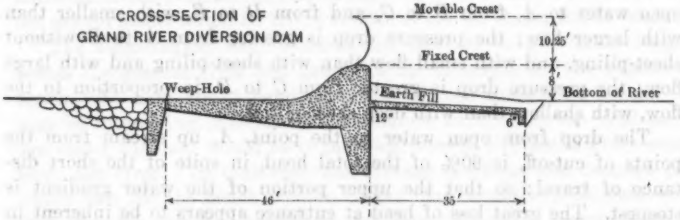

FIG. 18.

It may be stated that in this case measurements of uplift pressures were made through pipes placed in piers in the dam and ending in

pockets of screened gravel under the foundation. The results indicate complete absence of entrance losses. They also show drop of pressure to be closely proportionate to distance along line of creep. It should be stated, however, that owing to delay in placing movable gates, the heads at the time of the two measurements were in each case only between 4 and 5 ft., and that measurements under a full head of 18 ft. may give different results. Mr. Henny.

Experiments of the character made by the author must always be of intense interest to hydraulic engineers, and deserve full recognition.

JOSEPH JACOBS,* M. AM. SOC. C. E. (by letter).—This paper is of interest because it deals with an important engineering subject, concerning which there is all too little reliable information on which definite theory and judgment may be predicated. The author is entitled to credit for assembling the results of these tests for the use of the Profession, and for his frankness in presenting his interpretation and application of the facts disclosed. Mr. Jacobs.

The writer believes that the author failed to reach certain important conclusions, apparently fully warranted by the tests, and that in some respects his deductions as to the theory of underground water movements are fallacious. Particularly does he believe that the tests do not justify the conclusion, reached by the author, that the "line of creep" theory has been disproved.

In describing the initial seepage test in the 30-in. cylindrical tank (page 7), the author states:

"A valve at the bottom held back the water until the pore spaces were completely filled; then the valve was opened, and after a few minutes the relative elevation of the water in the two tubes became constant. The difference in elevation determined the loss of head, and from this the hydraulic gradient was computed."

* * * * * * *

"With 6 in. of water on the soil surface, and 8 in. of soil above the upper tube, the loss of head was 1 ft. in 9."

* * * * * * *

"Having determined the hydraulic gradient of the underground material, a trial design was made to find what dimensions would be necessary in a dam constructed wholly of this gravel."

These quotations, it seems to the writer, disclose a fundamental error in the author's application of his test. It will be noted that there is no mention of the quantity of seepage flow, and, as seepage flow and hydraulic gradient are inter-dependently related, the mention of one means nothing unless there is also included a definition of the other. The hydraulic gradient of 1:9, as found by the author, would appear to be a purely fortuitous result, for, with a variation in the size

* Seattle, Wash.

Mr. Jacobs. of valve opening (if it is less than the capacity of the gravel), and with variation in the depth of water above the soil surface, the ratio of loss of head to length of travel may be made to vary indefinitely. The maximum permissible limit of this ratio is that at which the seepage loss becomes prohibitive as to quantity, or at which the induced velocities are such that erosion or piping is threatened as a forerunner of the ultimate failure of the dam. It may be that the author decided that these requirements had been met in his hydraulic gradient of 1:9, but there is nothing in the text indicating this special consideration, nor do the seepage tests on the model dams seem to warrant such a decision.

It will be noted from the Second Series of Tests, which relate to the model from which the final dam was designed, that under a 10-in. head there was a mean seepage loss of approximately 0.0025 cu. ft. per sec. per lin. ft. of model dam. Bearing in mind that the model dam was built on a scale of 1:120 as compared with the final dam, and assuming, for the moment, that the hydraulic gradients and therefore the seepage velocities would be identical in the two, it follows that the seepage loss for the actual dam, under a condition of full reservoir, would be 360 cu. ft. per sec., made up as follows:

400 lin. ft. of dam under	100 ft. head, yielding	120 cu. ft. per sec.
1 600 " " " "	100 to 0 ft. head "	240 " " " "
Total rate of seepage flow at full reservoir		360 cu. ft. per sec.

This 360 cu. ft. per sec. would be further increased by reason of the hydraulic gradient in the actual dam being greater than that in the model. In comparing ratios of head to length of water travel, it is the friction head and not the total head that must be considered. In the model dam the 10 in. total head is greatly depleted by entry and exit heads, thus leaving a greatly reduced head available for friction losses, whereas, in the actual dam of 100 ft. head, the same quantitative depletion for entry and exit heads has relatively slight effect on the remaining friction head.

So great a loss as 360 cu. ft. per sec. from any reservoir would, of course, be prohibitive, even in the absence of any danger of undercutting the dam, and it must be assumed that the figures given in the paper are in error or that the author failed to apply the apparently clear inference to be drawn from his tests, which latter seems to be untenable because the tests appear primarily to have been suggested by the seepage difficulties encountered in the original dam. It would be interesting to have now a record of the actual behavior of the dam, as to seepage losses, if there has been opportunity for test since construction.

Mr. Jacobs.

Concerning entry head and exit head there is indication that the total head is affected by these elements, and it is this fact that renders difficult of interpretation the results obtained from experiments with small model dams, for in such dams the combined entry and exit heads may indeed form a relatively large part of the total head, though in dealing with full-sized dams they would form a relatively small or negligible part. To determine entry and exit heads from any set of tests, such as those by the author or by Mr. Colman,* we must first ascertain the friction head, and this in turn depends on the assumption as to line and resultant length of water travel along any film or differential element of flow. A critical examination of these tests shows a rate of loss of head due to friction that is not uniform per distance traveled, as measured between observed tubes. This disparity is due no doubt to variation in porosity and other mechanical elements of the pervious medium, and probably to some extent to observational errors, for it has been well established that, for an unchanging medium of this character, the rate of friction head consumption will be uniform. On the scheme of underground water movement, as hereinafter explained, the writer finds values of entry and exit heads in the Hays and Colman tests varying as follows:

In the Hays tests, with a total head of 10 in., entry heads varied from — 0.90 to + 5.98 in., the mean being + 5.5 in.; and exit heads from — 2.26 to + 0.45 in., the mean being — 0.9 in.

In the Colman tests, with an average total head of 54 in., entry heads varied from — 1.08 to + 21.36 in., the mean being + 7.0 in.; and exit heads from — 7.32 to + 13.08 in., the mean being + 3.4 in.

Because velocity is a function of all the elements which characterize the medium through which the water moves, it was thought that some relationship might be established between entry head and entry velocity, and exit head and exit velocity. The graphic method was used, but there was such lack of consistency in the results deduced from the tests that no dependable curves could be platted. Nor was this lack of consistency due to the particular scheme of water movement assumed, for other assumptions as to line and length of water travel showed similar inconsistencies. In the absence of more extensive data than we now have, we may only say at this time that there is entry head and exit head of uncertain amounts which must be reckoned with in experiments on small models, but which are negligibly small in dealing with full-sized dams.

All the formulas for the flow of water through soils are of the general form, $Q = c \frac{h}{l} a$, in which

* *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 421.

Mr. Jacobs.

Q = discharge;
a = area of cross-section;
$\frac{h}{l}$ = ratio of loss of head due to friction to length of water travel;
and c = a variable coefficient, dependent on water temperature, porosity, and mechanical analysis of the soil.

Water will follow the line of least resistance, and therefore that form of section and route of water movement will obtain which, for a given head, will afford a maximum discharge, or which, for a given discharge, will consume the minimum head. These conditions, as will readily be seen from the foregoing equation, in which c for any specific case is a constant, will be satisfied when $\frac{l}{a}$ is a minimum; and, in studying seepage and pressure problems, with respect to dams on porous foundations, we must first ascertain the form of section and route of water travel which renders $\frac{l}{a}$ a minimum.

It cannot be assumed that the water will be drawn from an indefinite distance up stream, nor released throughout an indefinite distance down stream, from the dam, for, if that were the case, Q would approach its minimum rather than its maximum, and $\frac{l}{a}$ would approach its maximum rather than its minimum value.

There may be, and doubtless is, some seepage draft from points far above, and seepage delivery to points far below, the dam, but the quantities would be negligible in comparison with the main body of seepage water, which, in the writer's opinion, based on mathematical analysis, would necessarily be drawn from, and delivered to, points in the immediate vicinity of the dam. The lengths of river-bed over which water draft and water release are operative, with respect to any dam, are important, because these lengths fix the hydraulic gradients on which pressure and seepage discharge depend.

The actual form of approach and exit channel for seepage, from free water above to free water below the dam, will depend on the base width of the dam, the depth of the pervious medium, the position of the cut-off wall, and the ratio of the depth of the cut-off wall to the depth of the pervious medium. If the approach is from free water above the dam to a full vertical section beneath the heel of the dam, the writer finds that, whatever its form, the minimum value of $\frac{l}{a}$ occurs when the distance up stream from the dam equals the depth of the pervious medium beneath the dam; that, of the various curves

Mr. Jacobs.

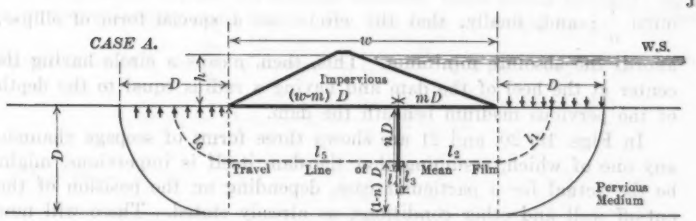

FIG. 19

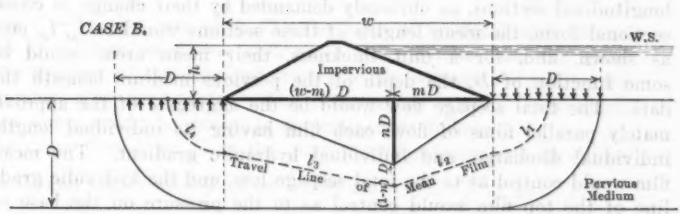

FIG. 20

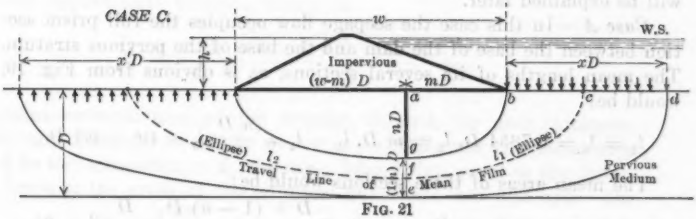

FIG. 21

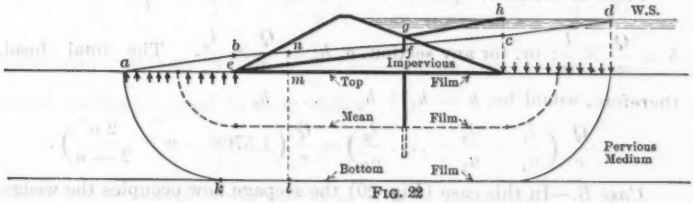

FIG. 22

Mr. Jacobs.

which might define the form of approach, the ellipse affords the minimum $\frac{l}{a}$; and, finally, that the circle, as a special form of ellipse, affords the absolute minimum. This, then, means a circle having its center at the heel of the dam and having a radius equal to the depth of the pervious medium beneath the dam.

In Figs. 19, 20, and 21 are shown three forms of seepage channel, any one of which, assuming that the dam itself is impervious, might be the actual for a particular case, depending on the position of the cut-off wall and other conditions, as already stated. These will now be examined: Referring to Figs. 19 to 21, consider a section of unit thickness normal to the paper. Dividing the seepage channel into longitudinal sections, as obviously demanded by their change in cross-sectional form, the mean lengths of these sections would be l_1, l_2, etc., as shown, and, for a unit thickness, their mean areas would be some function of D, the depth of the pervious medium beneath the dam. The total seepage flow would be the aggregate of the approximately parallel films of flow, each film having its individual length, individual discharge, and individual hydraulic gradient. The mean film would control as to the total seepage loss, and the hydraulic grade line of the top film would control as to the pressure on the base of the dam, except that, at and near the lower toe of the dam, in some cases, the hydraulic grade line of the bottom film might control, as will be explained later.

Case A.—In this case the seepage flow occupies the full prism section between the base of the dam and the base of the pervious stratum. The mean lengths of its several sections, as is obvious from Fig. 19, would be:

$$l_1 = l_6 = 0.7854\ D,\ l_2 = m\ D,\ l_3 = l_4 = \frac{n\ D}{2},\ l_5 = (w - m)\ D.$$

The mean areas of these sections would be:

$$a_1 = a_2 = a_5 = a_6 = D;\ a_3 = a_4 = \frac{D + (1 - n)\ D}{2} = \frac{D}{2}(2 - n).$$

From the original equation for seepage flow, $Q = c\frac{h}{l}a$, we obtain, $h = \frac{Q}{c} \times \frac{l}{a}$; or, for any section, n, $h_n = \frac{Q}{c} \times \frac{l_n}{a_n}$. The total head, therefore, would be, $h = h_1 + h_2 + \ldots . h_6$

$$= \frac{Q}{c}\left(\frac{l_1}{a_1} + \frac{l_2}{a_2} + \ldots . \frac{l_6}{a_6}\right) = \frac{Q}{c}\left(1.5708 + w + \frac{2\,n}{2 - n}\right).$$

Case B.—In this case (Fig. 20) the seepage flow occupies the wedge-shaped sections beneath the dam, and, in the space between the base

of the dam and the top of the seepage channel, there would be dead water, or approximately dead water. For this case we would have: Mr. Jacobs.

$$l_1 = l_4 = 0.7854\ D,\ l_2 = \frac{D}{2}\sqrt{4\,m^2 + n^2},\ l_3 = \frac{D}{2}\sqrt{4\,(w - m)^2 + n^2}.$$

$$a_1 = a_4 = D,\ a_2 = a_3 = \frac{D}{2}\ (2 - n).$$

$$h = (h_1 + h_2 + \ldots . h_4) = \frac{Q}{c}\left(\frac{l_1}{a_1} + \frac{l_2}{a_2} + \ldots . \frac{l_4}{a_4}\right)$$

$$= \frac{Q}{c}\left(1.5708 + \frac{\sqrt{4\,m^2 + n^2} + \sqrt{4\,(w - m)^2 + n^2}}{2 - n}\right).$$

Case C.—In this case (Fig. 21) the form of approach and exit is defined by ellipses, as shown, and, as in the previous case, the space between the base of the dam and the top of the seepage channel would be approximately dead water. The distance up stream from which seepage water would be drawn is determined as follows:

The mean film, $l_1 = fc$, is the quarter circumference of an ellipse the major and minor semi-axes of which are $a\ c = \frac{D}{2}\ (2\ m + x)$ and $a\ f = \frac{D}{2}\ (1 + n)$, respectively, and its length, according to the usually accepted approximate formula, would be

$$l_1 = \frac{\pi}{4}\frac{D}{2}\sqrt{\frac{(2\,m + x)^2 + (1 + n)^2}{2}}.$$

The cross-sectional area of the seepage channel, for unit thickness, would vary from $bd = xD$ to $ge = (1 - n)D$, and the mean area would be the area, *bdeg* $\div\ l_1$, the area, *bdeg*, being equal to the difference between the areas of the elliptical quadrants, *aed* and *agb*. The area, *bdeg* $= A = \frac{\pi\ D^2}{4}\ (m + x - m\ n)$, and $a_1 = \frac{A}{l_1}$. Therefore,

$$h_1 = \frac{Q}{c} \times \frac{l_1}{a_1} = \frac{Q}{c} \times \frac{l_1^2}{A} = \frac{Q}{c} \times \frac{\pi}{8}\left(\frac{(2\,m + x)^2 + (1 + n)^2}{m + x - m\,n}\right) \ldots (1)$$

To find the minimum value of $\frac{l_1}{a_1}$, differentiate and place the first differential coefficient equal to zero, thus,

$$\frac{\delta\ h_1}{\delta\ x} = \frac{Q}{c} \times \frac{\pi}{8}$$

$$\left(\frac{2\,(m + x - m\,n)\,(2\,m + x) - ((2\,m + x)^2 + (1 + n)^2)}{(m + x - m\,n)^2}\right) = 0.$$

Mr. Jacobs.

Clear of fractions, transpose, and reduce, and we have,

$$x^2 + 2m\,(1 - n)x = (1 + n)^2 + 4m^2n.$$

Complete the square, and we have,

$$x^2 + 2m\,(1 - n)x + m^2\,(1 - n)^2 = (1 + n)^2\,(1 + m^2).$$

Therefore,

$$x + m\,(1 - n) = \pm\,(1 + n)\,\sqrt{1 + m^2},$$

whence $$x = (1 + n)\,\sqrt{1 + m^2} - m\,(1 - n),$$

and this critical value of x proves to be the minimum rather than the maximum value of $\frac{l_1}{a_1}$. We would also have,

$$x' = (1 + n)\,\sqrt{1 + (w - m)^2} - (w - m)\,(1 - n).$$

Applying these values of x and x' to Equation (1), and reducing, we would have

$$h = h_1 + h_2 = \frac{Q}{c}\left(\frac{l_1}{a_1} + \frac{l_2}{a_2}\right)$$

$$= \frac{Q}{c} \times \frac{\pi}{4}\,(1 + n)\left[w + \sqrt{1 + m^2} + \sqrt{1 + (w - m)^2}\right].$$

Which one of the foregoing three cases would obtain for any actual dam would depend on the values of m, n, and w, but it would always be that one case, or that combination of the several cases, which would render $\frac{l}{a}$ a minimum. To determine this for any particular set of conditions is a simple computation, but a tabulation for varying values of m, n, and w, shows that, in most instances, Case A will obtain, and that Case C obtains only when m, n, and w are small. As between Cases A and B, when m is less than $0.66\frac{2}{3}$, the wedge affords the minimum $\frac{l}{a}$; when m is greater than 1.00, the prism affords the minimum $\frac{l}{a}$; and between these values of m, it may be either wedge or prism, depending on the value of n.

Now consider the question of the hydraulic upward pressure against the base of the dam: If the total head is known (as it would be in the cases considered), then its apportionment among the several sections of the seepage channel results from the general equation,

$$h = (h_1 + h_2 + \ldots\ldots h_n) = \frac{Q}{c}\left(\frac{l_1}{a_1} + \frac{l_2}{a_2} + \ldots\ldots \frac{l_n}{a_n}\right),$$

and would be as $$\frac{l_1}{a_1} : \frac{l_2}{a_2} : \ldots\ldots \frac{l_n}{a_n}.$$

Mr. Jacobs.

This apportionment, it will be noted, is independent of Q and c, for Q is necessarily the same for all sections, and c, too, is a constant, if the pervious medium be regarded as homogeneous throughout. If the medium is not homogeneous, and c is variable from section to section, then that factor would need to be retained in the computation, but the apportionment of head would still be fully determinable, if c were known for each section. This lack of perfect homogeneity tends to confuse the results in any study of the laws of underground water movement, and it is no doubt partly responsible for the variations and apparent disparities noted in the Hays' experiments.

In the top film of a seepage channel, the form of the channel having been determined, the lengths, l_1, l_2, etc., become known, and, as for the areas, a_1, a_2, etc., it must be assumed that, in this differential element of flow, the differential areas of the several sections bear the same relationship to each other as do the like whole areas of the whole seepage channel. The relative values, $\frac{l_1}{a_1}, \frac{l_2}{a_2}$, etc., thus become known, and the apportionment of the total head among the several sections of the top film, according to the method outlined in the previous paragraph, readily follows. From this determination of the heads, h_1, h_2, etc., the hydraulic grade line for the top film (and in similar manner for the bottom film) can be constructed, whence the computation for the hydraulic upward pressure proceeds by the proper evaluation of the area included between base of the dam and the higher of these grade lines; that for the bottom film, however, is subject to slight modification.

Referring to Fig. 22, it will be noted that *abcd* is the hydraulic grade line for the bottom film, and *efgh* for the top film, and that, for the section of the dam below the cut-off, the former appears to control as to the hydraulic upward pressure against the base of the dam. This is not necessarily so, however, nor do these hydraulic grade lines indicate the exact plane to which water would rise if the down-stream portion of dam were pervious, for there would be loss of head and pressure between the film considered and the final water plane, wherever it might be. The ordinate, *m n*, for instance, measures the head or hydraulic pressure of the bottom film at the point, *l*, whereas the actual pressure at *m* would be less than *m n* because of the loss of pressure between *l* and *m*, and because otherwise the water would tend to find escape in that direction rather than along the course, *lka*. The actual pressure line for the base of the dam due to the bottom film is probably little, if any, above that due to the top film, but the writer does not, at this time, know just how it can be located with assurance of entire accuracy.

Mr. Jacobs.

It will be noted that the validity of the "line of creep" theory is herein recognized, but that it does not have universal application. It obtains with respect to Case *A* when considering hydraulic pressures against the base of the dam, but does not apply to Cases *B* and *C*. In his examination of the author's tests (Case *A* applies), the writer finds nothing to upset the general theory developed in the foregoing, but, on the contrary, finds some confirmation in the fact that the average maximum departure of the observed from the writer's computed hydraulic grade line was only $\frac{3}{4}$ in. When it is considered that the author's tests show a computed variation in entry head of from — 0.90 to + 5.98 in., and in exit head of from — 2.26 to + 0.45 in., a departure of $\frac{3}{4}$ in. from a computed grade line should occasion no surprise. The uncertain effect of capillarity, undefined entry and exit resistances, variations in the mechanical analyses of the soil, and slight observational errors, would readily account for so inconsiderable a discrepancy.

On the whole, it may be questioned whether results from tests on such small-size models are of great value. The disturbing and relatively important effect of exit and entry heads, the possibility of inadequate box length to provide free approach and free exit of the seepage water, and other inherent limitations, certainly make the correct interpretation of the results extremely difficult. In the writer's opinion, the only acceptable confirmation of any theory as to the movement of seepage waters beneath dams, and the effect of cut-off walls thereon, must come from observation of full-sized structures actually built.

In closing, the writer would add that the following necessary conclusions are deduced from the general theory herein developed:

1.—That the form of computation for determining discharge and hydraulic grade line are similar to and practically as simple as those for pipe lines. With a reasonably accurate selection of the coefficient, c, in the first general formula, a reasonably accurate discharge, Q, can be predicted for any head of water above the dam, and a reasonably accurate hydraulic grade line can be platted for computation of pressures.

2.—That the cut-off wall must extend practically to an impervious stratum in order to reduce seepage loss appreciably. This fact is important in cases where seepage, by reason of its quantity, or its possible erosive action, must be considered.

3.—That, from considerations of both seepage loss and reduced hydraulic pressure on the base of the dam, the cut-off wall should be as near the heel of the dam as the local physical conditions will permit.

JAMES B. HAYS,* JUN. AM. SOC. C. E. (by letter).—The deep interest taken in the paper is ample evidence that many engineers are always on the alert for any bit of information pertaining to this subject. All members of the profession will welcome any information based on fact, either from field experience or models; although the former is greatly to be preferred, the latter will furnish subject matter for deep study in almost any case, aiding the designer to base his judgment on something more than guesswork. The writer's object, in making this model and testing it, was to apply the results, not directly, but toward forming some definite theory regarding the flow of water under dams. Mr. Hays.

On one point all the critics of the paper seem to agree in objecting to the results, that point being in regard to the size of the model, etc. There is only one factor that might vary with a larger model as compared with the small one, and that is in regard to the loss of head due to the water entering the soil.

The writer would earnestly suggest to all interested to try the method used in these experiments for obtaining the correct proportions of soil for the impervious section, whenever the occasion or chance should arrive. An extremely dense mixture will be obtained, and this, when properly placed, will hardly leave room for the hygroscopic moisture. When once saturated, the mixture will remain so for a long period, even though there is no water above the dam to force the water into it. This was the writer's experience. After soaking the model completely, the results did not seem to change, whether or not the model was left with a full head of water for 24 hours.

The writer has due respect for the "line of creep" theory, and realizes that many excellent structures have been built on that basis; but it certainly did not hold good for the upper row of sheet-piling, when the design is considered part by part; and, at the same time, the lower row of piling produced excessive results, which certainly were not caused by the upper row of piling being in place, other than that the total results were lower than if the lower row of piling had been the only one used. In other words, although the total results approached the "line of creep" theory, why did not either row of piling show a loss of head based on the same assumption? The only answer to this question, in the writer's opinion, is in the partly closed valve theory.

Imagine a pipe line with two valves; close the lower one nearly half way, and then close the upper one only one-eighth of the whole distance. The discharge is lessened, the velocity through the main portions of the pipe is lessened as a result, but the lower valve (corresponding to the lower sheet-piling) creates no small loss of head (assuming that the water is passing through the pipe and not standing still), which is represented by a high velocity through the valve. The upper valve does not have its full effect, does not produce the loss of head that it would were

* Boise, Idaho.

Mr. Hays.

the lower valve not closed. The reason is that the water velocity is lowered by closing the lower valve for the entire pipe, consequently the quantity is less, and hence a lower velocity or loss of head is required at the upper valve to pass the smaller quantity of water, when compared with the original discharge. It is quite evident that the upper valve does not have the same effect on the lower one, although it does assist in lowering the total discharge. If the lower valve were closed still more, by an amount equal to the closing of the upper valve, and the upper valve were opened, the total loss of head would be greater than for the two valves partly closed, as just described.*

Extend the piling cut-off deep enough to leave only a very small opening between the bottom of the pile and bed-rock, and we have, horizontal 745 ft., vertical $2 \times 239 = 478$ ft.; then the total creep is 1 223 ft., and the gradient is 1:12.23. The loss of head due to the piling would be about 39 ft., whereas the actual loss of head could not fail to be far greater than the above figure. Extend the piling still deeper, leaving an infinitesimal opening under the cut-off for the water, and the results will depart still farther from the "line of creep" theory.

It was for this reason that the writer discarded this theory, when it failed to hold out, and accepted the "partly closed valve" theory, which explained thoroughly the results obtained with the model.

There must be a limit to the "line of creep" theory somewhere, but it is not mentioned in any of the standard works discussing the subject. Weisbach's experiments show that a gate-valve closed seven-eighths produces a loss of head nearly 47 times as great as when closed only half way, the "line of creep" theory, under the same conditions, shows that the loss of head due to closing down seven-eighths is only one and one-half times the loss produced by closing half way.

That the leaky condition of the upper row of sheet-piling should be plainly visible from a great distance, and not to the experimenters, is strange. Attention is called to the notes below Tables 2 and 3.

The low heads reported for the points, *H* to *K*, were taken simultaneously with the readings for the other tubes, and the drain valve was closed, during all experiments and between days, and the leakage from the tank was nil.

All gravel larger than 1½ in. in diameter was removed from the material placed in the bottom of the tank, and 1 in. was the limit allowed for material in the section of the model. This was done in order to eliminate leakage surfaces for the water to follow, as they would be all out of proportion to the size of the model.

The quantity of water entering the vertical circular tank was the same as that leaving the drain at the time the readings were made. Time was allowed for the water to adjust itself to the conditions.

* "Treatise on Hydraulics", by Merriman, Art. 88; also *Transactions*, Am. Soc. C. E., Vol. XXVI (1892), p. 449.

Lowering the head on top of the soil in the vertical tank caused the water to lower in both tubes by the same distance. It was determined definitely that the water was not held up in the tank sufficiently to affect the readings of the lower tube at any time. Mr. Hays.

Water did not flow through the drain valve during the experiments on the model, as Mr. La Rue seems to have understood; this would have defeated the experiments entirely. Instead, the water-table was forced up to within a short distance of the ground surface below the dam to represent the actual conditions, as nearly as possible. Practically all the material comprising the foundation of the dam at the actual site is saturated. There is a definite underground stream flowing down the valley.

Where the upward pressure against the base of the dam was mentioned by the writer, it was meant to be inferred that it was the pressure on an imaginary plane, just as one would speak of the hydrostatic pressure at a certain point in a body of water.

Evidently Mr. Petterson disregards the writer's idea of making the down-stream section of the dam more stable by having a very small upward pressure beneath that portion, whereas, in designs such as Fig. 14, a very high percentage of the material in the down-stream section is thoroughly saturated, because the hydraulic gradient is close to the surface. Assuming in both cases that a cut-off wall through the main portion of the structure will cause all percolation water to come under the dam, the hydraulic gradient is in both cases projected at a slope of 1:10, beginning at the toe and extending up stream. In Fig. 15 the lower 225 ft. of the down-stream section just covers the hydraulic grade line. Mr. Petterson has taken his hydraulic grade line below the base of the dam apparently to indicate the upward pressure on the base, or the imaginary plane which we call the base. The water will rise in the body of the dam to an extent governed by the upward pressure at any point. Where y and z or y' and z' are respectively equal or nearly equal, it is readily seen that the water will rise in the body of the dam to the line as shown, z or z' above the base. Thus, the hydraulic grade line for the lower portion of the down-stream section of the section shown in Fig. 15, will be identical with the surface of the material constituting the dam. In an earth dam this would certainly be disastrous. Continue the gradient at the rate of 1 on 10 for the next 175 ft. under the portion with the 1 on 2 slope, and it will be observed that a large portion of this down-stream section will undoubtedly become saturated. Of the down-stream section of Fig. 15, it is computed that 453 cu. yd. per lin. ft. of material will be dry, that is, above the hydraulic gradient (1:10). Fig. 17, which corresponds to the writer's second section, shows that 717 cu. yd. per lin. ft. of material in the same section will be dry. Mr. Petterson's argu-

Mr. Hays. ments on this point convince the writer, more than ever, of the advisability of having as much material as possible in the down-stream section dry, in order to secure stability. Figs. 14 and 16 can be compared in the same manner, showing even greater advantages in favor of the latter, as very little of the material in Fig. 14 will lie above the hydraulic gradient. Material below the hydraulic gradient will lose about 50% of its weight, which might be exerted toward increasing

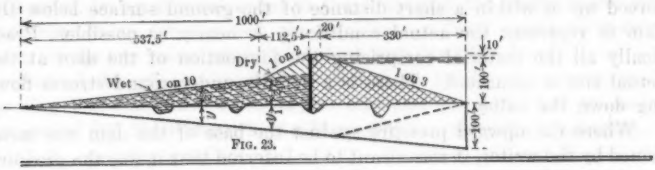

FIG. 23.

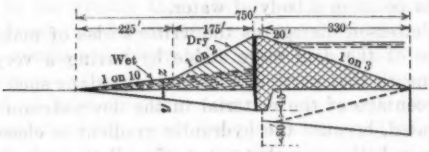

FIG. 24.

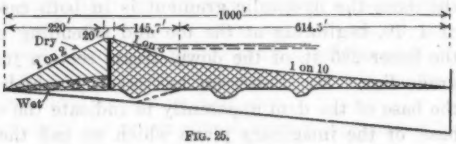

FIG. 25.

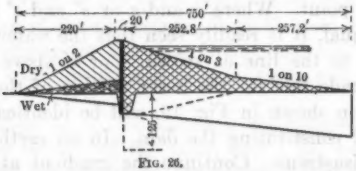

FIG. 26.

stability, due to buoyancy. Using Figs. 14 to 17, the writer has prepared Figs. 23 to 26, on which the hydraulic gradients are drawn through the down-stream section, in order to show the dry and saturated sections in each case.

Regarding the possible underflow to be expected under the finished structure, it would seem that several engineers have jumped to conclusions in this matter. Assume that the water flows through the

foundation material of the dam in the same manner as through a large bundle of very small pipes. These pipes will have such a small diameter that capillary action will have a great effect proportionately, and the velocity of the water will be so low that the discharge will vary directly as the first power, rather than the square—this being an elementary rule in hydraulics. The length of flow and the increased head in the proposed final structure will be proportionate, hence there will be the same loss of head per unit of distance along the base of the dam; but multiplying the area through which the discharge takes place will produce different results from those obtained by taking the required number of bundles of pipes. Two pipes having the same total area as a larger pipe will not have the same capacity as the larger pipe—assuming, of course, that the loss of head per unit distance is the same in each case. The velocity is higher in the larger pipe, with the same loss of head per foot, than in the two smaller pipes. Mr. Hays.

Many of the criticisms of the tests are well taken, but the writer hoped for more discussion containing real meat, rather than theory. It will undoubtedly be a long time before anything definite can be decided which will furnish a sound basis for sheet-pile cut-off walls, under similar conditions, other than the information now available. As mentioned previously, the "line of creep" theory is not yet to be discarded, but it has not yet been practically proved, except as regards the fact that dams, well built, and following that theory, have stood the test. Actual records of the loss of head due to piling seem to be lacking, and this is what the writer wanted to know when the tests on the model were attempted. He is firmly convinced that tests on a large model of the same structure would show similar results, aside from the entry head.

Paper No. 1380

UNDERPINNING TRINITY VESTRY BUILDING FOR SUBWAY CONSTRUCTION*

By H. de B. Parsons, M. Am. Soc. C. E.

With Discussion by Messrs. James C. Meem, Elias Cahn, T. Kennard Thomson, James F. Fouhy, Charles Rufus Harte, Joseph A. A. Connelly, J. S. Branne, A. W. Buel, and H. de B. Parsons.

Synopsis.

This paper describes the underpinning of the Vestry and School Building of the Corporation of Trinity Church, which was made necessary by subway construction.

The building is on Church Street, between Fulton and Vesey Streets, Borough of Manhattan, New York. It is a brick structure with thick walls, having four floors, basement, and part attic, and was constructed about 30 years ago.

The Church Street subway curves at Fulton Street and passes beneath the building and beneath the Churchyard of St. Paul's Chapel to Vesey Street. The subway structure consists of two circular tunnels, each 20 ft. in diameter. The tops of these tunnels are just beneath the level of the footing stones of the building. As the tunnels run diagonally beneath the building, it was necessary to remove its original foundations entirely, to construct new foundation piers, and to transfer the load of the building to these new piers by means of cross-girders.

* Presented at the meeting of October 4th, 1916.

The paper describes how this work was done, and how the new foundation piers were sunk so as to cause the least disturbance to graves and vaults.

The brick walls of the building were first strengthened by fastening to them heavy lattice girders on each side, and, on the Fulton Street face fastening two 60-in. plate girders in a similar manner.

Excavations for the new underpinning piers were made at selected intervals, so that the settlement of the building could be kept under control.

The paper describes the use of concrete underpinning piles, and gives the results of a number of tests made to determine their bearing capacities. These tests showed that the piles had a tendency to rebound when pressure was relieved, and the paper describes how this element of weakness is overcome when such piles are used for underpinning.

The method of tunneling through the sand beneath the Churchyard and building is described.

Surveys were made before the work was undertaken and after it was finished, and these showed that the subway construction work caused the building to settle approximately 2 in., which was fairly uniform on account of the manner in which the underpinning piers were sunk.

The contract price for 1 000 ft. of this subway construction work was $982 740. The work commenced in June, 1913. Both tunnels were completed in June, 1914. The basement floor of the building was restored to the owners by October, 1914. The final restoration of the whole property was practically finished in April, 1916.

As the underpinning of the Vestry and School Building of the Corporation of Trinity Church was an unique example of protection work, made necessary by subway construction in New York City, the writer presents the following description which he hopes will be found of interest by many.

The chief features of this underpinning were the entire removal of the original foundations, the construction of new foundation piers to an elevation below the sub-grade of the tunnels, and the transference of the load of the building to these new piers, without interfering with its occupancy or use.

The building is on the west side of St. Paul's Churchyard, and faces on Church Street between Fulton and Vesey Streets. Fig. 1 is a general view of the building, which shows clearly its chief characteristics and the proximity of the Churchyard, with its graves and vaults.

The building is of brick, having four floors, basement, and a part attic. It has a gabled roof, with side gables, or dormers, all having slopes of 45 degrees. The walls are 2 ft. thick above the water-table, and 2 ft. 9 in. below that level. The floor-beams are supported on the outside walls. In addition to these outside walls, about 100 ft. of interior walls also carry weight. The floors are surfaced with wooden or mosaic flooring, according to the use of the various rooms. The building is of heavy construction, and was completed about 30 years ago.

The subway, known as Route 5, was designed to run north on Church Street as far as Fulton Street, then to curve eastward beneath the Vestry Building and the Churchyard to Vesey Street, and then to curve again to the northward into Broadway. A special agreement was entered into between the Vestry of Trinity Church and the Public Service Commission, representing the City of New York, whereby the Vestry gave the City, under certain restrictions, a right of way for the purpose of constructing tunnels for a rapid transit railway beneath the Church property. The right of way was deeded to the City, as the Vestry realized that this subway work was part of a great municipal improvement.

The City was given possession of the basement for 18 months, so as to facilitate the work of construction, and agreed to build new foundations capable of carrying a new building of eight stories or one of lighter construction not exceeding ten stories.

Fig. 3 is a plan of the building, and shows the positions of the east and west tunnels beneath the building and the proportion of the foundations cut away by them. The tops of these tunnels were just beneath the level of the footing stones under the building walls, as shown in Fig. 4.

An examination of the building was made before any work was done; its condition was carefully noted, and all defects or cracks were recorded. Survey marks were made at various places around the exterior walls, and their elevations taken.

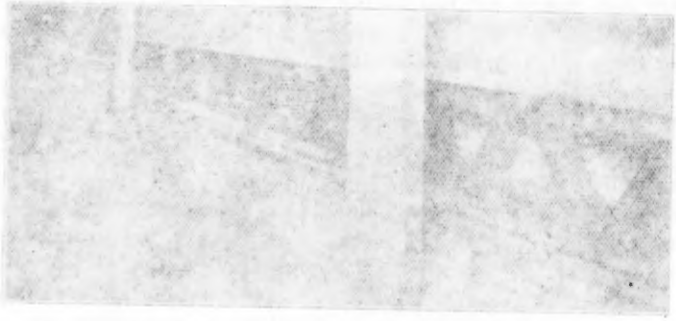

FIG. 1.—GENERAL VIEW OF TRINITY VESTRY BUILDING AND ST. PAUL'S CHURCHYARD.

FIG. 2.—LONGITUDINAL LATTICE GIRDER BEING ERECTED AND FASTENED IN PLACE.

The following are the dimensions of the building:

Length on Church Street	164 ft. 0 in.
Width on Fulton Street	35 ft. 0 in.
Width on Vesey Street	48 ft. 0 in.
Length of exterior walls	428 ft. 0 in.
Area of ground plan	6 055 sq. ft.
Area of one floor (less walls)	5 340 sq. ft.

The following are the estimated weights:

Exterior walls	7 950 000 lb.	= 3 975 tons.
Interior walls and partitions	994 000 "	= 497 "
Floors	773 000 "	= 386.5 "
Plastering, ceilings and walls	797 000 "	= 398.5 "
Roof construction	393 000 "	= 196.5 "
Equipment, trim, plumbing, etc.	501 000 "	= 250.5 "
Live load, maximum	1 378 000 "	= 689 "
Total weight on foundations,	12 786 000 lb.	= 6 393 tons.

The area of the original foundations was:

Under exterior walls	2 140 sq. ft.
Under interior weight-bearing walls	400 " "
Total area of foundations	2 540 sq. ft.

The unit loading on the original foundations, assuming the weight to be distributed uniformly over the footings, therefore, was 2.51 tons per sq. ft.

The soil was sand, varying in places from fine to moderately coarse. Mean high water level was 23 ft. below the street, but the ground-water was found about 4 ft. 6 in. above that level. Pumping in the adjacent subway excavations reduced the ground-water to about high water.

After conferences, the City agreed that the new foundations should be able to support the building if four new stories of similar construction were added, or their equivalent in weight. These additional floors were estimated at 3 907 tons.

Original weight of building	6 393 tons.
Additional weight, agreed upon	3 907 "
Estimated load for new foundations	10 300 tons.

FIG. 3.

This estimated load on the exterior walls (10 300 tons divided by 428) equals 24 tons per lin. ft.

As the load would be supported principally by the side exterior walls, it was arbitrarily agreed that the underpinning under the side-walls should carry more weight and under the end-walls less weight than the average; or

End-walls	12	tons per lin. ft.
Side-walls.	28	" " " "

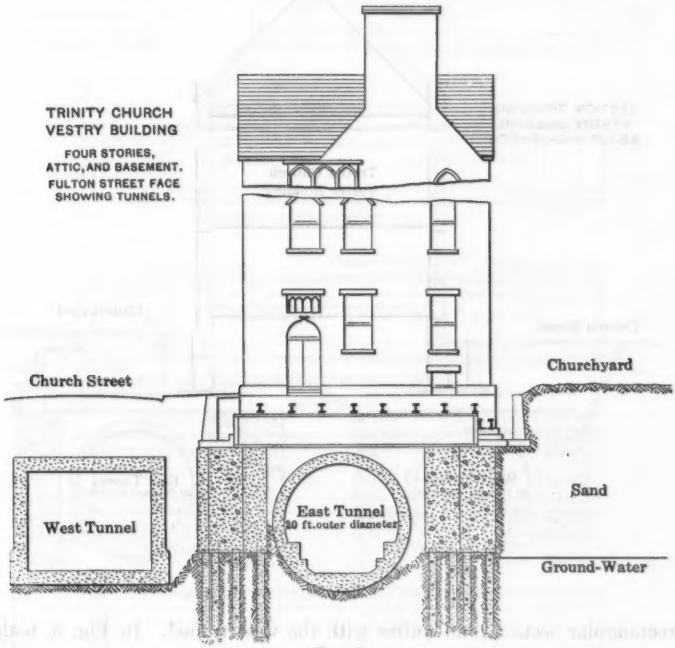

FIG. 4.

The plan for underpinning finally adopted consisted of sinking 115 pits, each 5 ft. square, under and around the building, but placed so as to clear the tunnels, as shown in Fig. 3. These pits were then filled with concrete. Girders were designed to span the tunnels, and were placed across the concrete piers in such a way that they would pass under the walls of the building. The load of the building was then

gradually transferred to these piers, or to the girders and by them to the piers. This plan will be better comprehended by referring to Fig. 4, which is a section at the Fulton Street face, and Fig. 5, which is a section through the building at about mid-length.

In Fig. 4, the west tunnel is under Church Street, clear of the building, and has reverted to the standard rectangular section. The east tunnel is just emerging from the building. It then changes to a

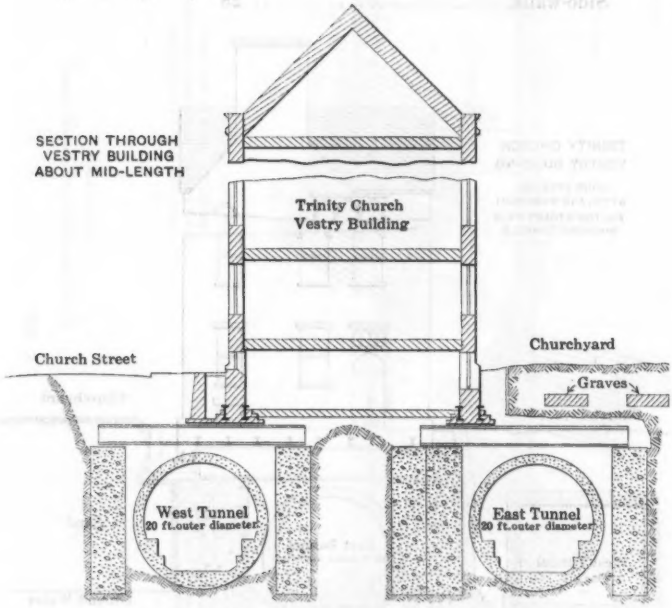

FIG. 5.

rectangular section, and unites with the west tunnel. In Fig. 5, both tunnels are under the building, or Churchyard, and are of circular section.

The first operation was to fasten 24-in. lattice girders on each side of the foundation walls. These girders are marked *L* 2, in Fig. 3, and are shown in detail in Fig. 6. At Fulton Street, the 24-in. girders were reduced to 12-in. so as to make room for the cross-girders marked *G* 5, in Fig. 3. These 12-in. lattice girders are marked *L* 1. The func-

FIG. 6.

tion of these longitudinals was to strengthen and tie the brickwork together, that is, to make it more monolithic in character. The brick walls were thus enabled to distribute the loads from above over longer lengths, and to span safely the openings which were to be dug subsequently for the concrete underpinning piers.

At one place on the Church Street side, 24-in. longitudinal plate girders, 20 ft. long, were used in place of the 24-in. lattice girders. These are marked *L* 3, in Fig. 3. This change in design was made so that the load of the side-wall could be carried over a space left between nests of cross-girders, which had to be placed diverging, so that their

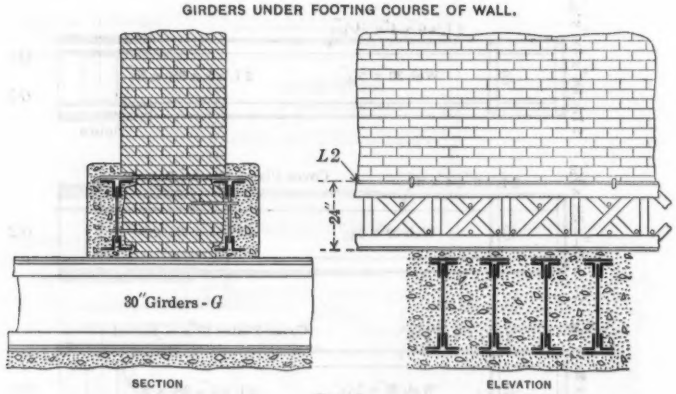

FIG. 7.

concrete piers could clear a foundation of an elevated railway column in Church Street.

Projections on the sides of the footing walls were cut away, leaving the vertical surfaces somewhat rough. This cutting was done by both hand-drills and by power channel drills. Grooves were cut for the angles of the top and bottom chords, in order that the girders could fit snug against the walls.

The girders were then doweled to the walls at frequent intervals. The dowels were square rods driven into the walls and bent over to catch the framing of the girders. Ties also were inserted in holes drilled through the wall at intervals. These bound the top chords of

the inside and outside girders together. The arrangement is illustrated in Figs. 7 and 8. After the girders were in place they were embedded in concrete, a strong bond being secured by the friction of the roughed surfaces of the sides of the walls aided by the dowels. To facilitate the placing of these girders, they were built up in place and bolted. Splices were staggered, both of the upper and lower chords and of parallel girders. Fig. 2 shows a 24-in. longitudinal lattice girder in process of erection. It is similar to those used under the Vestry Building.

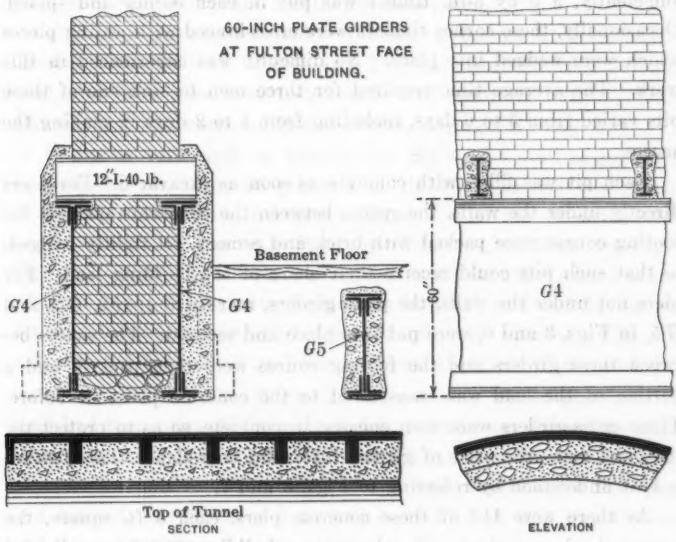

FIG. 8.

Across the Fulton Street face, two 60-in. plate girders were used in the same manner as the side lattice girders. These 60-in. girders are marked *G* 4, in Fig. 3, and were made in three parts for convenience in placing, the sections being bolted together when in position. They were tied together by 12-in. I-beams, 40 lb. per ft., as shown in Fig. 8, and were encased in concrete. The weight of the wall was transmitted to the girders by these needle I-beams, as it was not deemed wise to rely on the bond of the concrete casings.

After completing the work of fastening the longitudinal girders, *G* 4, *L* 1, *L* 2, and *L* 3, excavations for the underpinning piers were commenced. Excavations for adjacent piers were not made at the same time. When one pit was started, the next would be 30 or 40 ft. away, or as far as convenience would allow.

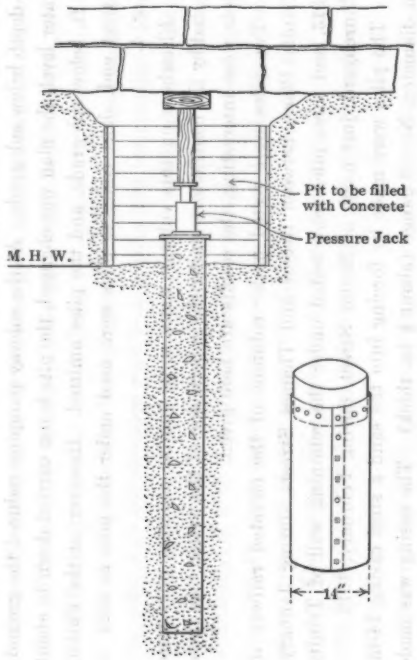
The pits were sunk by hand digging. As the excavations proceeded, the sides were box-sheathed with 2-in. planks laid horizontally. These planks were cut to fit, and when a set of four was in place the pieces were toe-nailed at the corners. When an excavation had advanced sufficiently, a 3 by 3-in. timber was put in each corner and spiked. Occasionally, these corner timbers were cross-braced with waling pieces which were wedged into place. No difficulty was experienced in this work. The average time required for three men to sink one of these pits varied from 3 to 6 days, including from 1 to 2 days in making the access.

Each pit was filled with concrete as soon as excavated. For piers directly under the walls, the spaces between the concrete tops and the footing course were packed with brick and cement, all tightly wedged, so that such pits could receive their share of the building load. For piers not under the walls, the plate girders, marked *G* 1, *G* 2, *G* 3, and *G* 5, in Figs. 3 and 6, were put into place and secured. The spaces between these girders and the footing course were then packed, and a portion of the load was transferred to the concrete piers, as before. These cross-girders were then encased in concrete, so as to protect the steel and make the nests of girders into solid floor-slabs. This feature is best understood by referring to Figs. 3 and 7.

As there were 115 of these concrete piers, each 5 ft. square, the average load on each was, for the present building (6 393 tons divided by 115 times 25) = 2.22 tons per sq. ft.; or, for the assumed future building, would be (10 300 tons divided by 115 times 25) = 3.58 tons per sq. ft.

In the Churchyard, some of the graves and vaults were in the way of the pit excavations. To avoid disturbing them, cross-tunnels were routed in from convenient sides, at sufficient depths to clear the graves, as shown in Fig. 5. When the correct locations were reached by the cross-tunnels, the pit excavations were carried down vertically in the usual manner.

It was the original intention to excavate the pits for the concrete piers to about ground-water level and then to drive concrete piles to a depth below sub-grade. As the subway pumping reduced the ground-water level, the plan was changed, the pits being carried down to about 1 ft. below sub-grade, and the piles omitted. However, at the Fulton Street end, short concrete piles were used under the pits, as seen in Fig. 4.



Elsewhere on this subway route some similar concrete piles were tested by the contractors, under the supervision of the writer. As these tests were interesting, the results are here given.

Two piles were tested under columns of the elevated railway in Trinity Place, between Rector and Thames Streets, during January, 1913, and three piles were tested under the retaining wall of Trinity Churchyard, just north of Rector Street, during February, 1913.

The piles were made by forcing into the sand a steel casing 14-in. in diameter, No. 12 gauge (about $\frac{1}{8}$ in. thick). The casing was made in sections about 24 in. in length, each section having an inside sleeve so as to permit one section to fit on top of the one just below, see Fig. 9. The steel casing was sunk by a pile-driver until its upper edge was level with the sand; then a new section was inserted, and the driving was continued until the proposed depth of pile was reached. The sand was removed by a small grab-bucket from the inside of the casing as the sections were sunk. When the entire casing was in place and the sand had been removed from the inside, the pile was formed by filling the casing with 1:2:4 concrete. For filling below ground-water, the concrete was put in paper bags and the bags were lowered into place and tamped. After about 2 ft. had been filled in this way the concrete was placed by a bottom self-dumping bucket.

The piles were tested, after the concrete had set, by a hydraulic jack, using the footing courses of the foundations as a base against which the jack was blocked. Owing to the short stroke of the jack, the pressure had to be relieved and the blocking readjusted as each pile sunk under the test loads. Whenever the pressure was relieved, there was a slight rebound of the pile. A graphic representation of Test IV is shown in Fig. 9, which illustrates this rebound.

Test I.—Steel casing, 9 in. outside diameter, driven inside a 14-in. casing which had buckled. The pile was 15 ft. long, and projected

Test II.—This test was made to measure the end resistance of a 9-in. outside diameter, pointed casing. A 14-in. steel casing, 12 ft. long, was first sunk, and about 2 ft. of sand allowed to remain at the bottom. Inside this casing a steel pile 9 in. in diameter, 14 ft. 6 in. long, of ½-in. steel, with cast-iron point, was driven until the point was below the outer casing. Neither casing was filled with concrete. The soil was fine, wet sand.

* Pressure relieved, to reset blocking under jack.
† Rebound, when pressure was relieved.

Some conclusions, deduced from a study of the test loads and penetrations, are:

(1) The initial loads, which the piles supported before sinking, were variable.

(2) The sinking increases more rapidly than the load.

(3) When the pressure is relieved, the pile rebounds.

(4) When the same load is again put on the pile, the penetration is greater than the original penetration, that is, the pile sinks more than its rebound.

(5) The supporting power of one of these concrete piles depends chiefly on the area of its base. The side friction in sand probably does not exceed from 5 to 8% of the load.

(6) To secure the maximum supporting power without additional settlement, a concrete pile should receive its permanent load while under pressure, that is, the permanent underpinning load should be transferred to it without relieving the test load.

(7) This latter condition can be accomplished by placing struts between the footing to be underpinned and the pile top before the pressure of the jack is relieved.

After the underpinning work had been completed, and the load of the Vestry Building had been transferred to its new foundations, excavation beneath the basement was commenced, and the tunnels were

allowed to advance toward the building. At the same time, excavation under Church Street, which had been decked with wood, also was being made.

The tunneling commenced from a shaft in Vesey Street, and the east tunnel was kept somewhat in advance of its westerly mate. Both tunnels were worked forward from Vesey Street across the Churchyard toward Fulton Street. They are 20 ft. in outside diameter, and are lined with cast-iron plates covered with concrete inside.

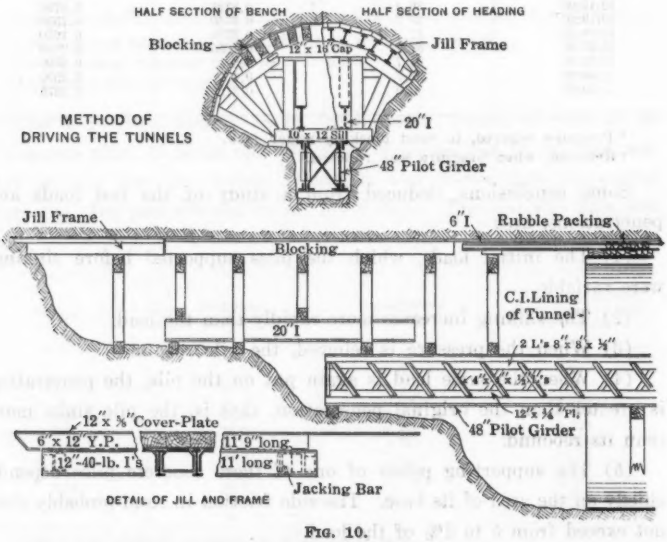

FIG. 10.

As the soil was sand, varying from fine to medium coarse, the method of tunneling adopted by the contractors is shown in Fig. 10. Jills, arranged side by side in the curve of the roof, and supported by cap timbering, were driven forward by jacks. As the jills were pushed ahead, the space behind them was sheeted and filled with blocking resting on the caps. The sides of the tunnel were sheeted with 2-in. planks, held in place by braces and struts. A steel pilot girder formed the base from which the various braces and capping were supported. This pilot girder also formed the truss for supporting the centering machine which raised and put the cast-iron lining sections in place.

The excavation was carried forward by an advance drift close under the roof, and benches formed by deeper excavations to sub-grade were kept back at safe distances, depending on circumstances. Timbering was placed as the section was enlarged, and the cast-iron lining plates of the tunnel were erected as soon as the full section was cut. Fig. 11 shows one of the headings as it advanced under the Churchyard.

The jills were made of timber, sheathed with steel plates bent over the forward nose to form a cutting edge. These jills rested on, and were bolted to, steel frames, built up as seen in Fig. 10, and were all supported on timber capping braced radially from the tunnel center. They were pushed ahead by hydraulic jacks, the center one being kept slightly in advance of the others. The sand was removed in cars to the Vesey Street shaft and hoisted to the street.

The tunneling was accomplished without serious accident, although the method required great care and attention to prevent slips. There was a noticeable loss of sand, that could not be avoided, and there was a slide of sand at one place which caused a marked settlement of the Churchyard. The engineers of the Public Service Commission approved the tunneling plans before work started, and the contractors are entitled to credit for the manner in which the work was done. The tunneling beneath the Churchyard was accurately carried forward, and the headings entered the spaces between the concrete foundation piers as planned.

When the drift reached the partial excavation beneath the building, the advancing jills, as they emerged from the sand, are shown in Fig. 12.

Fig. 13 shows the excavation beneath the building. The concrete foundation piers are seen on both right and left, and the concreted cross-girders are shown overhead. The cast-iron lining of the tunnel can be seen in the background. As the lining plates were erected, the spaces around them were back-filled.

Fig. 14 is another view of the excavation beneath the building. The basement windows can be seen through an opening between the concreted cross-girders.

Fig. 15 shows the east tunnel at Fulton Street, with the concreted cross-girders, *G* 5, overhead. At the top of the picture in the foreground is seen the footing course of the Fulton Street wall of the building.

Fig. 16 is a view inside the completed cast-iron lining of one of the tunnels. It shows the concrete key of the inside lining which was jacked into place in advance of the general lining.

The work of underpinning and of transferring the load to the new piers caused a settlement of the building, as shown by the surveys, as follows:

At N.E. Corner, on Vesey Street	$1\frac{1}{16}$ in.
" N.W. " " " "	$1\frac{5}{16}$ "
" center of Churchyard side	$1\frac{3}{16}$ "
" " " Church Street side	$2\frac{5}{16}$ "
" S.E. Corner, on Fulton Street	$2\frac{3}{16}$ "
" S.W. " " " "	$2\frac{3}{8}$ "

A few cracks of minor importance developed, and the plaster spalled in some places.

As shown by the survey figures, the settlement was very uniform. This even settlement, and the slight damage to the building, resulted from digging the pits without regularity, that is, by not excavating them from one end of the building toward the other.

The contract price for this section of the subway, extending from a point on Broadway, just north of Barclay Street, to Church Street, a distance of 1 030 ft., was $982 740.

The work of underpinning was commenced in June, 1913. The longitudinal girders along the wall footings and the cross-girders were all placed by February, 1914. Both tunnels were completed beneath the building by June, 1914. The back-filling under the building was completed and the basement floor and rooms restored by October, 1914, or 17 months after the active work of underpinning was started. The final restoration of the property was delayed by the work under Church Street, requiring the adjustment of street steam-supply pipes, telephone ducts, sewers, etc., until April, 1916.

The contractors were Frederick L. Cranford, Inc., and the work was done under the personal direction of Mr. F. L. Cranford and J. C. Meem, M. Am. Soc. C. E.; the Superintendent on the work was Mr. H. L. Robinson, and the Assistant Engineers were Messrs. H. P. Moran, in charge of the office, and W. McI. Wolfe, Assistant Engineer on field work. For the Public Service Commission, Alfred Craven,

The photographs were taken by Mr. Edwin Levick.

DISCUSSION

Mr. Meem. JAMES C. MEEM,* M. AM. SOC. C. E. (by letter).—The author has covered the subject of this paper so ably and fully that very little remains to be said, except in reference to the elaboration of certain points which he has mentioned.

The sectional roof shield method of tunneling has been used on many important pieces of work, and is doubtless familiar to many, but the use of the "pilot-girder" in connection therewith is new. This was made of two lattice-girders, 4 ft. high, cross-tied and braced to form a continuous box-girder, the rear members, as stated, being carried forward and placed in position as required. The outer chords were made longer than the inner ones, in order to accommodate it to the curvature of the tunnel. The office of this girder was to carry the falsework over the bottom excavation between the heading and the completed section of the tunnel, and it proved to be a very satisfactory and efficient substitute for the arched timber method which had generally been used in connection with the sectional shield.

Owing to the shortness of the radius of curvature of this tunnel and the extreme accuracy with which the rings had to be set (the contractor was limited absolutely to a variation of not more than 2 in. at any point), it is doubtful whether any other method of tunneling could have been used so successfully and advantageously.

In the matter of the concrete key in the roof, which is shown in Fig. 16, very satisfactory results were obtained by filling beforehand these spaces in the cast-iron ring above the key. Heretofore, as far as the writer knows, no satisfactory method of filling these spaces after placing the key has been found, except by grouting. This key was placed by using a form with a movable bottom; on this the concrete was placed and then the whole mass was jacked into the roof space and maintained until it had set.

In the matter of the very limited dependence to be placed on skin friction resistance of piles, as noted by the author, the writer agrees very heartily. He believes that skin friction resistance is often mixed up with bearing resistance, and that, as a factor by itself, it has very little value, especially with smooth-bore piles. To assume a value of, for instance, 1 000 lb. per sq. ft. for skin friction resistance, as many engineers often do, is to assume that the pile withstands an external pressure of approximately 2 500 lb. per sq. ft. It is improbable, however, except in cases of very long piles in deep fluid strata, that piles are ever subjected to a pressure of more than a few pounds per square foot, and if this is true, skin friction resistance, of course, can be only a fraction of this pressure, so that, as stated, it may be neglected

* Brooklyn, N. Y.

in nearly all cases. The pile, undoubtedly, derives its real support from the so-called "bulb of pressure" at its base. Mr. Meem.

ELIAS CAHN,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with great interest, particularly the part relating to the tests on concrete piles, and considers the Profession greatly indebted to the author for their publication. It is a pity, however, that these valuable tests were not extended to include the influence of other factors bearing on the supporting power of these piles and their settlement under load, no less important than those considered. Time is one of these factors, and should not be neglected in dealing with earth, because stresses travel so slowly through this medium. All the tests, particularly No. 5, give indications of this, but the time taken in any of them, about 1 hour, is very far from sufficient to develop this influence fully. The depth to which a pile is driven is also an important factor. Mr. Cahn.

The following, therefore, are suggested as additions to the author's conclusions:

(8) The settlement accompanying the development of a certain pressure will be greater, the longer the time taken to develop this pressure.

(9) A pile will settle under the action of a constant pressure at a rate and for a time depending on the pressure, the area of the base of the pile, the kind of material which the pile penetrates, and the surcharge over the horizontal plane through the bottom of the pile.

The earth immediately under the pile, when subjected to the maximum pressure of the jack, as is clearly indicated by the rebound, is in a state of excessive compression, which undoubtedly decreases in all directions from this point. There will be a tendency to equalize this compression in time, thereby reducing that immediately under the pile, and either decreasing its resistance or causing further settlement.

The conditions under which equilibrium is finally obtained and the total settlement in time under a definite pressure or load, are the determinants of what the safe load should be, rather than the pressure it is possible to develop with the jack in a short time.

In Conclusion (5) no mention is made of the effect, on its supporting power, of the depth to which the pile is driven. This depth, for any given earth, determines the compression that the material under the pile will stand permanently, and therefore the load it will support.

The practice of considering the safe load as one-half the maximum pressure obtained with the jack, therefore, is not logical unless the depth of penetration and the kind of earth as well as the area of the

* New York City.

Mr. Cahn.

base of the pile are considered in determining the pressure to be obtained with the jack. Aside from any difference in the skin friction, a pile driven 30 ft. into the earth would have a greater supporting power than if driven only 15 ft., though the same pressure is obtained with a jack in the manner described in the paper, simply because the earth at the lower level will stand permanently a greater degree of compression than at the upper level.

The author has done more than his share in conducting the tests recorded, and it is to be hoped that those who may have the opportunity in the future will continue where he has left off, clearing up this matter of the effect of time and of depth of penetration on the settlement of a pile under a constant pressure after the earth under it has been compressed by a far greater pressure.

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—It is a pleasure to see a well-designed piece of work well carried out, and then well described; and the Society is once more indebted to Mr. Parsons.

Whenever the writer sees a "jack" under a building he thinks of the comments of an eminent lawyer who was wont to laugh at engineers for their careless use of the English language, for he claimed that they nearly always referred to the process of "jacking up the building"; whereas, they did not do anything of the sort, as the method was to put a jack between the base of a building and a post or sill resting on the ground and then, by operating the jack, force the post or sill into the ground, keeping the building itself exactly where it was, instead of "jacking it up".

Sentimental reasons against disturbing the church building and graveyard undoubtedly entered into the selection of this design. The contract price, as stated by the author, was $982 740 for 1 000 ft. Otherwise, it might have been cheaper to tear down the old building instead of underpinning it. However, the occupants of the building and countless thousands of pedestrians gained by the lack of disturbance of surface conditions.

It was fortunate in this case that two of the most dangerous elements, often encountered in underpinning operations, were absent—that is, water, and bad design or construction of the building to be underpinned.

The speaker recalls one building which caused him much worry, due to its very defective—to say the least—construction. It was some twelve stories high; the two lower floors were supported by cast-iron and steel columns of various shapes and the floors above were carried by brick walls. The first joint uncovered disclosed the fact that two 20-in. beams did not rest on the shelf brackets of the cast-iron columns, as there was at least a 2-in. space between the bottom of the I-beams

* New York City.

Mr. Thomson.

and the top of the shelf, and although there had been provision for several bolts to connect the flange of the columns to the webs of the beams, only one bolt, for each beam, had been put in place—so all the support which the heavy 20-in. I-beams had was one ¾-in. bolt each. If a safe or any other heavy article had ever been moved over these beams, there would have undoubtedly been a bad collapse.

Needless to say, the disclosure of such an unsafe condition in the first joint uncovered caused much worry about the possible condition of the many joints in the building, which it was not possible to uncover for examination. However, the building, which rested on quicksand, at the surface of the ground-water, was safely underpinned by forcing cylindrical caissons to bed-rock from 60 to 70 ft. below the water surface, through New York quicksand.

The speaker has underpinned walls eighteen stories high, by putting cylindrical caissons down by the Breuchaud method, through 70 ft. of water and quicksand, and then constructing a cellar for the new building 35 ft. under water.*

In underpinning a six-story building by jacking down 16-in. pipes until they were supposed to have reached hardpan (as a matter of fact they offered so much resistance to the jacks that the weight of the old building was really taken off the old foundations, as shown by horizontal cracks in the brickwork), it was found, after all the sand had been washed out of the cylinders and they had been filled with good concrete, which should have made the underpinning strong enough to carry very much heavier loads than those to which they were subjected (for the building was practically raised by jacking against the empty pipes, that is, before they had been filled with concrete) that the cylinders actually settled when the pneumatic caissons were being sunk near-by, thus loosening up the soil around the pipes and thereby destroying the friction. It would seem, therefore, that dependence cannot be placed on such pipes when the surrounding material is likely to be disturbed.

The author states that in the Trinity Vestry Building the friction of the material around the pipes was disregarded, and that the pipes were treated as short columns having all the load transmitted to the base, but these pipes were comparatively short. The length of such cylinders is often 30 ft. or more; they are too long to be considered as short columns, and offer very considerable resistance, due to the friction of the earth.

Owing to this lack of reliability, the speaker does not usually recommend underpinning with cylinders, unless they are large enough to permit a man to enter them to excavate the material and then fill them with concrete. A cylinder having an outside diameter of 30 in. is about the smallest that can be used for this purpose.

*A full description of this work was published in *Engineering News*, March 28th, 1901.

Mr. Thomson.

It pays to use an ample thickness of metal in the cylinders, for the speaker has seen them made so thin that it was impossible to see the bottom of the excavation from the top, owing to the warping of the pipes while being jacked down.

On removing some old buildings on Wall Street, New York City, which, about 14 years previously, had been underpinned by 14-in. pipes jacked down and filled with the best of concrete (paper bags having been used there also), except for the bottom 2 ft. of the cylinder, it was found that it had been impossible to pump out all the sand, and the concrete had probably set without thoroughly compressing the sand in the lower 2 ft. of the pipe.

This, of course, would allow the building to settle at least a few inches, if it ever happened that the friction of the soil against the pipe was insufficient to carry the load, as is often the case when the soil is disturbed.

In underpinning, as in other foundation work, no hard-and-fast rules can be laid down, as each building requires a treatment of its own.

The author refers to the rebound of the cylinders after the jacks were removed, and the method taken to prevent it. The usual method, however, is to use steel wedges, either between steel plates and beams, or between granite wedging blocks.

The speaker tested some open concrete caissons for a bridge in New Jersey a few years ago, and measured the rebound. The cylinders were of reinforced concrete 6 ft. 6 in. in diameter, having an open well, about 3 ft. 6 in. in diameter from the bottom to the top, to permit the material to be excavated by clam-shell buckets.

After the caisson had penetrated some 75 ft., and was resting on what was supposed to be fairly good sand, it was filled solid with concrete to the top, which was 87 ft. from the cutting edge, making a solid concrete pier, 6 ft. 6 in. in diameter, from 12 ft. above ground to the cutting edge.

After this had stood for some time, a load of steel rails was gradually applied until a maximum of 10.24 tons per sq. ft. on the base of the pier was attained.

A gradual settlement of $\frac{5}{8}$ in. resulted, and, when the load was removed, the rebound was $\frac{1}{4}$ in., leaving a supposed permanent settlement of $\frac{3}{8}$ in. As this settlement had been caused by applying 10.24 tons per sq. ft., and as the total weight of the bridge, with its live load, would not exceed 6 tons per sq. ft., it would seem that the piers would be perfectly safe. As a matter of fact, however, the jar of the trains started fresh settlement in a number of the piers, and this continued for about one year, when the maximum of 6 in. was reached. This was about 5 years ago; and since then there has been no trouble.

Strange to say, the piers which settled were those which were supposed to rest on the best material. Mr. Thomson.

The speaker once constructed a tunnel 7 ft. in diameter, by the poling-board method, under Cedar Street, New York City, and then ran a branch tunnel 4 ft. in diameter for 104 ft. up the street. The 7-ft. tunnel was just below the sewers and other pipes, and just above the water line at the bottom, as about 6 in. of very damp sand had to be handled. The work was done so carefully that there was absolutely no settlement in the street, and, as a matter of fact, nobody except those concerned in the construction knew that the tunnel had been built.

It might be interesting to mention the fact that in Michigan, where there are mining shafts 4 000 ft. or more in depth, it has been noted that heavy weights dropped from the top of the shaft never reach the bottom, as the revolution of the earth causes them to strike the side (always the same side) of the shaft, and become lodged there. This was first noticed when a very heavy weight was accidentally dropped from the top and it was feared that the men in the shaft must have been killed, but the men did not even know that anything had fallen, because it never reached the bottom.

JAMES F. FOUHY,* ESQ.—The speaker would like to know Mr. Parsons' opinion as to whether or not the rebound of the piles was due to looseness at the joints of the pile sections. Such rebound can hardly be attributed to loose joints when the piles are concreted. The speaker has tested numerous piles recently before placing the concrete filling. The sections were from 12 to 16 in. in diameter, $\frac{5}{16}$ in. thick, and from 7 to 12 ft. long. Tests up to 40 tons were made with piles in clay, and 80 tons with piles on rock. In all the tests, the rebound was noted, and it is not unlikely that play at the joints was responsible therefor. Mr. Fouhy.

CHARLES RUFUS HARTE,† M. AM. SOC. C. E.—The speaker would like to know whether the rebound occurred immediately after the pressure was removed, or whether it was some time afterward that the piles showed a tendency to come up? Mr. Harte.

In connecting the Providence Division of the New York, New Haven and Hartford Railroad with the South Station, at Boston, Mass., in 1889, the necessity of maintaining traffic on the important streets crossed led to the use of a pile-driver with very short leaders, and sectional piles, which were made by sawing ordinary piles into 10-ft. lengths and fitting the lower end of each piece with a wrought-iron ferrule about 12 in. long, and a central dowel of 2-in. pipe. A special driving head, consisting of a heavy ferrule with a short section

* New York City.
† New Haven, Conn.

Mr. Harte. of pile, received the direct blow of the drop-hammer and protected the upper end of each section; as soon as a section was flush with the ground, this head was removed, a new section fitted on it, the head put on the upper end, and the driving continued until the pile was seated in the hard clay from 40 to 60 ft. below the surface. The material overlying the clay was salt marsh mud stiffened by the ashes, earth, and other filling material with which the Back Bay district had been reclaimed; it flowed laterally and vertically as displaced by the piles, forming a mound in some cases 2 or 3 ft. higher than the original surface, and, through the skin friction, opened the joints of the piles already driven, causing the tops to come up in some cases nearly 1 ft.

This adjustment of pressure extended over some little time, but, as a rule, if the piling of a group was tapped by the driver 48 hours after the last pile was driven, there was no further movement.

With sand, however, as in Mr. Parsons' case, the speaker would not expect such delayed action. The Boston fill had decided elasticity, which here would be lacking.

Mr. Connelly. JOSEPH A. A. CONNELLY,* ASSOC. M. AM. SOC. C. E.—If the speaker understood Mr. Parsons correctly, he has stated that the load used in testing the piles was from 40 to 50% in excess of the required load. He has also stated that the pile was jacked down under this excess load, was held in place by the jack, and that the load of the superstructure was then wedged hard down on the pile, so as to prevent any motion. The speaker presumes the motion referred to was the rebound of the pile.

Assuming the required load on the pile to be 40 tons, the load under which the pile would be jacked down and held in place would be 60 tons. The speaker would like to know how a pile under a pressure of 60 tons can be held in place by a superstructure load of 40 tons. It is very probable that even 40 tons is in excess of the load which the pile actually receives from the building, while the 60 tons is actually placed on the pile by the jack.

It has been suggested that the rebound may be due to motion at the joints of the pile, but, in the speaker's opinion, this is not the case. On work of which he has had charge, steel casings, filled with concrete, were driven to a depth of 34 ft. These casings were made up of seventeen 2-ft. sections, and thus there were sixteen joints in each pile. As in the cases mentioned by the author, the piles rebounded about $\frac{1}{4}$ in. when the jacks were released. If all this rebound was due to motion at the joints, and was considered to be equally divided, the movement at each joint would be $\frac{1}{64}$ in.; this, in the speaker's opinion, is too small to lend much support to the theory that pile rebound is due to joint motion.

* New York City.

Mr. Connelly.

A statement has also been made that a pressure of 77 tons was sustained by an empty pile made up of short steel sections; this pile resistance, under conditions such as those outlined in the paper, seems to be high; one would be led to suspect that an obstruction had been encountered.

Mr. Branne.

J. S. BRANNE,* M. AM. SOC. C. E.—The speaker wishes to ask Mr. Parsons' opinion as to the behavior of the steel-cased concrete piles.

It is stated in the paper that the piles rebounded after releasing the pressure exerted by the jack which had forced them down. It seems to the speaker that this rebound is due, in a large measure, to lack of skin friction in these piles—the surface being a smooth steel plate—and that this would not occur in piles with a rough surface, as in a concrete pile cast and seasoned before driving, or even in a wooden pile, the latter having more or less knots and irregularities. The material through which the piles were forced is stated to have been coarse sand, and this should have offered quite some resistance to rebound. The speaker believes that, in a soft clay soil, there would be a rebound, due to the elasticity of the soil and the lubricating influence of the moisture in the clay.

Referring to the jill frames which were driven forward with jacks, the speaker would like to know how large a section of frame was pushed forward at one time, that is, how wide a section; and also how much pressure was required to push such section forward? In case of an unusual obstruction, as, for example, a large boulder, the speaker supposes that such obstruction would be removed by the laborers with picks and shovels.

Mr. Buel.

A. W. BUEL,* M. AM. SOC. C. E.—The speaker would like to know whether it is possible that a part of the rebound is due to the elastic recovery of the pile itself?

With a modulus of elasticity, E_c, taken at 2 000 000, the elastic recovery of a pile, 14 in. in diameter and 40 ft. long, under a load of 40 tons, would be 0.01 ft., or $\frac{1}{8}$ in.

$L = 40$ ft.;
Diameter $= 14$ in.;
Area $= 154$ sq. in., nearly; and
$P = 40$ tons $= 80\,000$ lb.

Then, if E_c is assumed at the usual value of 2 000 000, there will result:

$$f = \frac{P}{A} = \frac{80\,000}{154} = 520 \text{ lb. per sq. in.}$$

$$\text{Deformation} = \text{elastic recovery (nearly)} = e = \frac{f\,L}{E_c}$$

$$= \frac{520 \text{ lb.} \times 40 \text{ ft.}}{2\,000\,000} = 0.0104 \text{ ft., or } \tfrac{1}{8} \text{ in.}$$

* New York City.

Mr. Buel. The average final rebound, of the four tests in which it was recorded, appears to have been 0.2715 in., or slightly more than ¼ in. The elastic recovery of the pile itself is shown to be just about one-half of this, if the modulus of elasticity is taken at 2 000 000. Considering the conditions under which the concrete is placed, it would not be surprising if the modulus were less than 2 000 000, in which case the elastic recovery of the pile itself would be a still larger proportion of the total final "rebound". The remainder of the final rebound—probably not more than ⅛ in., and possibly less—might be just as well described and explained as the "elastic recovery" of the material supporting the pile, as to call it a "readjustment of the particles". In the last analysis, there may not be much distinction between the two descriptions or explanations, but if the phenomena can be explained by the action of well understood properties of matter, there would not seem to be any good reason for seeking new theories.

If the figures given by the speaker are correct, and the rebound is due, in about equal parts, to the recovery of the pile and of the material supporting it, then both would be of about equal importance. The records of the five tests indicate stress-strain relations not very different from those characteristic of concrete columns. This would naturally be expected, as both the concrete and the supporting material are imperfectly elastic and, like the concrete, the supporting material probably has a variable modulus of elasticity.

[Mr. Parsons. H. de B. Parsons,* M. Am. Soc. C. E. (by letter).—The writer will endeavor to make clear some of the points raised in the discussion.

Replying to Mr. Harte: The rebound of a concrete pile occurred as soon as the pressure was removed. In other words, the top of the pile rose while the hydraulic pressure was being relieved from the jack. When all the pressure was relieved, the rebound ceased.

Replying to Mr. Connelly: Concrete piles used in subway underpinning work, as described in the paper, are designed to carry safe loads, but are tested to loads in excess of the permanent safe loads. Thus, a building pier might support a load of 200 tons. If each pile were intended to carry 40 tons, there would have to be at least five piles beneath the pier. In such a case, each pile could be safely tested to a load in excess of 40 tons and be held in place under such a load. When the last pile was tested, it would temporarily relieve the excess loads from the others.

Although there is nothing in the paper which refers to a pressure of 77 tons on an empty pile made up of short steel sections, pressures as great as this are sometimes developed in sinking the empty steel casings.

Replying to Mr. Branne: Each jill-frame consisted of three 6 by 12-in. timbers, making the wooden part about 36 in. in width, sup-

* New York City.

ported on an iron frame composed of two 12-in., 40-lb. I-beams, about 18 in. centers, as shown in Fig. 10. Only one jill-frame was pushed forward at a time, and the center frame was kept slightly in advance of the side frames. The pressure used in moving a frame naturally varied owing to local resistances. The frames were moved by 3½-in., hydraulic rams, and the average pressure to start a frame was about 5 000 lb. per sq. in., but this fell, as the frame moved, to about 3 000 lb. per sq. in. Mr. Parsons.

Referring in general to the remarks on the rebound of the concrete piles: It can be stated that the rebound was not attributable in any way to looseness of the joints of the steel casings. The function of the steel casings was to hold back the sand and to act as a form for the concrete. The loading was placed on the concrete and not on the casing.

The rebound may be due in part to the elastic recovery of the concrete, as mentioned by Mr. Buel, although his estimate for the modulus of elasticity is probably somewhat low. The rebound apparently was caused by the particles of sand under and around the foot of the pile readjusting themselves as the pressure on the pile was reduced. This "elastic recovery" of the sand and the "elastic recovery" of the concrete are probably both intimately connected with the rebound, although with present knowledge it is not possible to tell how much is due to the one and how much to the other.

Paper No. 1381

SURGES IN AN OPEN CANAL

By R. D. Johnson, Esq.

With Discussion by Messrs. Karl R. Kennison and Irving P. Church.

Synopsis.

This paper points out a rational theory on which to base research into the question of the rise of water in a canal following an interruption of flow, due, for example, to a shut-down of a water-power plant; it calls attention to the analogy between this surge and the phenomenon known as the "hydraulic jump".

This interesting subject always comes up in connection with the problem of how high to build fore-bay walls to avoid overflow in case the motion of the water in a canal is suddenly arrested by a short circuit. Trouble from this source seems to be very infrequent, and yet a sound theory for the computation of the height of the surge wave has never come to the writer's attention. The reason that wash-overs have not been more common seems to be due to the fact that, for ordinary velocities, the surge is comparatively small, and a good fair guess usually proves a sufficient safeguard; nevertheless, it may be interesting to set forth what appears to be the beginning of a sound theory, applicable to such cases.

Neglecting friction, in a smooth, rectangular flume, the sudden dropping of a gate would seem to cause a backward rolling wave which consumes a part of the energy of the oncoming water in eddy losses, and accounts for the remainder in an increased depth behind the wave,

the water standing still and level between the wave and the gate. On this theory, an equation from which the depth of the water may be determined is expressible through recourse to the well-known law that force is equal to the rate of change of momentum; for, if the depth of the water in motion is d and that of the water at rest is D, the total free force acting (for unit weight of fluid and unit width of flume) is $\frac{D^2 - d^2}{2}$ and, in the time, t, during which Qt cubic feet of water passes, with a velocity, v, and also Qt cubic feet of water is projected backward over the top, so to speak, of the oncoming stream, the quantity of water brought to rest is Dt multiplied by the velocity of propagation of the wave, or,

$$Dtv_3 = Dt \times \frac{Q}{D - d},$$

the change of momentum is

$$\frac{DQtv}{g\,(D - d)},$$

and the rate of change of momentum is

$$\frac{DQv}{g\,(D - d)},$$

whence,

$$\frac{D^2 - d^2}{2} = \frac{D\,d\,v^2}{(D - d)\,g} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

from which D may easily be determined by trial.

It may be observed that as velocity is only relative, the height of the "jump" which takes place in this case should agree exactly with the formula for the "hydraulic jump", if the proper corrections are made in the velocities relative to the earth, in such manner that the wave would "stand still" in the ordinary acceptation of the term. In other words, no error in theory is introduced if, while the above phenomenon is in progress, the whole flume is regarded as moving, bodily, with a velocity, relative to the earth, equal and opposite to that of the wave propagation; and such modifications ought to, and do, reveal the formula for the ordinary "hydraulic jump".

In this case, the absolute velocity of the water approaching the wave would be

$$v + \frac{Q}{D - d} = v_2$$

and the absolute velocity of the deeper water, at depth, D, would be

$$\frac{Q}{D-d} = v_1, \text{ and } v_2 - v_1 = v, \text{ as before.}$$

The new quantity, $Q' = D\,v_1 = \dfrac{Q\,D}{D-d}$.

The formula for the hydraulic jump is,

$$\frac{D^2-d^2}{2} = \frac{Q'}{g}(v_2 - v_1)$$

and as D and d are unchanged, we may substitute for the foregoing values of v_2, v_1, and Q', their equivalents in terms of Q and v, as follows:

$$\frac{D^2-d^2}{2} = \frac{Q\,D\,v}{g\,(D-d)} = \frac{D\,d\,v^2}{(D-d)\,g},$$

thus disclosing the identity of the two formulas and justifying, to some extent, the reasoning outlined in the premises.

To complete the analogy, it may come to mind that, as water cannot "jump" unless it has a velocity greater than $\sqrt{gd}$, it would be well to demonstrate that the sum of the velocities, v and v_3, is always greater than $\sqrt{gd}$.

Note, from Equation (1), that,

$$\frac{v^2}{g} = \frac{(D+d)\,(D-d)^2}{2\,D\,d}$$

and we are to show that

$$v + v_3 \text{ or } \frac{v\,D}{D-d} > \sqrt{gd},$$

that is, that

$$\frac{v^2}{g} > \frac{d\,(D-d)^2}{D^2},$$

or, eliminating $\dfrac{v^2}{g}$, that

$$\frac{D+d}{2\,d} > \frac{d}{D},$$

which is obvious so long as $D > d$.

The surge, S, above the level of the quiet water previous to its acceleration into the canal entrance is evidently equal to $D - d - \dfrac{v^2}{2\,g}$, and it may be shown by calculus methods that the maximum possible

value of S is equal to $0.714d$, which occurs for a critical velocity of $v = 7.448\sqrt{d}$.

Modifications Involving Friction.—It now seems clear that Equation (1) represents the relation between the depths on each side of the backward rolling wave when friction is neglected. Without attempting to go further into the subject at this time, it may be stated, nevertheless, that the surge probably cannot exceed the value of S derived from this equation, when friction is taken into account. On the other hand, there would seem to be little danger of extravagance if the height of the canal and forebay walls was regulated by the foregoing considerations.

DISCUSSION

Mr. Kennison.

KARL R. KENNISON,* ASSOC. M. AM. SOC. C. E. (by letter).—The author's determination of the height of the surge in an open canal, following a sudden interruption of the flow, appears to be based on sound theory. It is particularly interesting to the writer on account of the intimate relationship between this surge and the hydraulic jump, the discussions of which are published with the writer's paper "The Hydraulic Jump, In Open-Channel Flow at High Velocity".† The author's treatment of the hydraulic theories involved is complete, and requires little to be said in addition. The same conclusions, however, may be reached in a different way, at the same time bringing out some interesting characteristics of the hydraulic jump which were suggested by reading this paper; also, a formula for the canal surge is submitted herewith which is simpler than that deduced by the author.

There are points of difference between the ordinary hydraulic jump or standing wave and the author's receding wave which at first seem inconsistent, but which are really in agreement. It has already been shown† that in an open channel, carrying a certain quantity of water under a certain head, there are only two surface levels at which the water can flow steadily. If the velocity is less than $\sqrt{g \times \text{depth}}$, it is flowing at the upper alternative stage, and, if a dam of the proper height is interposed, it will drop to the lower alternative stage. If the velocity is greater than $\sqrt{g \times \text{depth}}$, it is already at the lower stage, and may jump to the upper stage by meeting either an obstruction, which, if of the right height and smoothness, may avoid all but incidental eddy losses, or a change in channel conditions sufficient to cause the normal jump with its eddy losses, as ordinarily observed. The question may arise: how can the level in a low-velocity canal, which is already at the upper alternative stage, jump any higher on the sudden closing of a gate, even higher than the level of quiet water before its acceleration into the canal entrance, as the author states?

The explanation is that the conclusions previously drawn, with reference to the hydraulic jump, assumed that the jump was in every case stationary, not moving up or down stream. Now, if this standing wave travels along the channel, we may, since velocity is only relative, correct all the velocities by an amount equal to the velocity of the wave, and then the conclusions regarding the hydraulic jump apply correctly to all such moving waves. For example, a suddenly interrupted canal flow, though flowing apparently at the upper low-velocity stage, is approaching the (receding) wave at so high a relative velocity that it is relatively at the lower

* Providence, R. I.

† *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 338.

Mr. Kennison.

stage and capable of jumping higher. In fact, when we consider the standing wave or jump as movable along the stream, instead of stationary, there are, instead of two, an indefinite number of possible water levels. It can even be shown that absolutely still water in an open channel can theoretically be made to drop to any lower level or to rise to any higher level by the passage of a standing wave.

This relationship between the hydraulic jump and the surge in an open canal is already clear to one who has followed the author's admirable mathematical analysis. At the risk of some uninteresting repetition, an attempt is made to say the same thing in a different way, and also to show graphically some peculiarities of the hydraulic jump and its relation to the canal surge. The writer has found that elementary diagrams like these are often helpful in getting a clear idea of the subject.

In Fig. 1, two smooth obstructions or dams are assumed to be kept a uniform distance apart and moved along the bottom of a rectangular flume containing still water, with the result that the water level drops, as shown, and rises again to still water, neglecting, of course, friction and incidental eddies. The dimensions are chosen so that direct comparison may be made, if desired, with Figs. 3 to 8 in the writer's paper, "The Hydraulic Jump, In Open-Channel Flow at High Velocity". Higher dams moved at lower velocity would cause a drop lower than shown, and lower dams at higher velocity a drop not as low. The same height of dams, moved much more slowly than shown, would cause only a local depression over each dam. They could not be moved faster without raising the level of the still water ahead, until their velocity is increased to that shown in Fig. 2. Then the water would rise theoretically as shown and drop again to still water, neglecting friction and incidental eddies, which, of course, would actually be considerable at this velocity. In Fig. 3, one of the dams is replaced by a gate; and, in Fig. 4, the other dam is removed, resulting in a case exactly similar to the suddenly interrupted canal flow described by the author.

All velocity being relative, the absolute velocities in Fig. 4 are also expressed relative to the velocity of the standing wave, illustrating the normal hydraulic jump, and also relative to the gate, illustrating the canal surge. These four figures are not necessary to show this relation, but they may prove interesting in a study of the hydraulic principles involved.

It is apparent, therefore, that to find a general expression (neglecting friction) for the resulting depth, D, in a channel of rectangular cross-section in which the water, flowing with depth, d, and velocity, v, is suddenly checked, it is merely necessary to take Professor Unwin's formula for the hydraulic jump,* which is in excellent agreement with

* *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 410.

Mr. Kennison.

experiment and is apparently based on sound theory, and substitutes for the velocity before the jump its value in terms of the difference in velocities before and after the jump. The result checks exactly with the equation deduced independently by the author. Since this

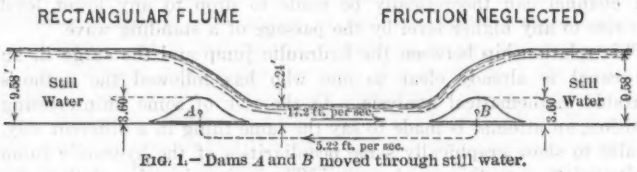

FIG. 1.—Dams A and B moved through still water.

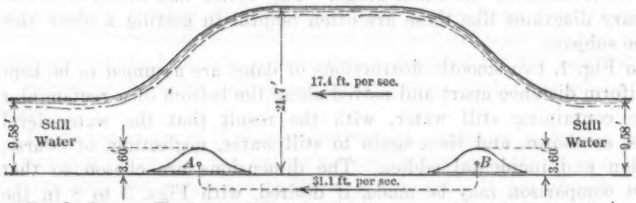

FIG. 2.—Same as Fig. 1, except that A and B are moved about six times as fast.

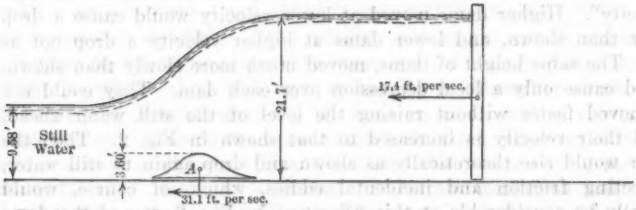

FIG. 3.—Same as Fig. 2, except that B is replaced by gate moving about half as fast.

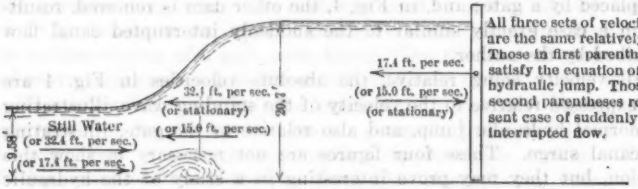

FIG. 4.—Same as Fig. 3, except that A is removed so that jump, instead of occuring without loss of head, contains the normal jump losses, the surface is not lifted so high, and the standing wave travels faster.

is a cubic equation, it cannot be solved easily, except by trial. The following simple equations will probably be found more convenient. They are not mathematical equivalents of the Unwin quadratic equation for the hydraulic jump and the author's cubic equation for the

Mr. Kennison.

canal surge, but, as shown by Table 1, for all reasonable uses, the error is well within the precision attainable in hydraulic computations of this nature. d is the depth, in feet, and v is the velocity, in feet per second, in a rectangular (frictionless) flume. D is the depth after the jump.

For the hydraulic jump or standing wave:

$$D = \frac{v\sqrt{d}}{4} - 0.45\,d \quad \ldots\ldots(1)$$

For the receding wave caused by sudden interruption of flow:

$$D = \frac{v\sqrt{d}}{5} + 0.99\,d \quad \ldots\ldots(2)$$

Mr. Church.

IRVING P. CHURCH,* ASSOC. AM. SOC. C. E. (by letter).—As regards the very interesting problem involved in this paper, on the surge produced in a nearly level, open canal of rectangular section, in which water is initially flowing with uniform velocity, when a vertical gate is suddenly dropped and completely closes the channel, the writer recalls no prior treatment in English, except as found on the last page of an article by Mr. Ford Kurtz.† In his treatment, however, in applying the method involving "change of momentum" Mr. Kurtz inadvertently used the mass of the flow per second of the water approaching the advancing surge and as yet unaffected by it, instead of the mass suffering impact per second, in forming his expression for the rate of change of momentum; that is (in his notation), he wrote $\frac{\gamma\, b\, h_1\, v_1}{g}$, instead of $\frac{\gamma\, b\, h_1}{g} \times \frac{l_1}{t}$. Had he used the latter expression, he would have arrived at a result identical with Mr. Johnson's Equation (1).

Turning to French sources: Flamant‡ gives the following demonstration (here modified for a channel of rectangular section and

* Ithaca, N. Y.

† "Application of Newton's Second Law of Motion to Certain Hydraulic Problems". *The Cornell Civil Engineer*, January, 1916. Published at Cornell University, Ithaca, N. Y.

‡ "Hydraulique", p. 415, Second ed., Paris, 1900.

Mr. Church. constant width, b, and with some of the notation of the present paper). See Fig. 5.

Let AB be a rigid vertical plate, or gate, entirely closing the end of a straight horizontal channel of rectangular section and constant width, b, which contains water at rest, extending indefinitely to the right, and of depth, d. The plate is at right angles to the sides of the channel. Let the plate now assume instantaneously a velocity of U feet per second toward the right, this velocity being then maintained at constant value. The water near the plate acquires (in small installments) the same velocity, U, and is heaped up in front of it with a flat top and constant depth, D, the front edge, $C''C$, of this wave (wave-front) moving toward the right with some constant velocity, V. Let $D - d$, or the height of the wave, be denoted by h. If γ is the weight of a cubic unit of water, the total horizontal pressure (above atmospheric) between the plate and the raised water is $\frac{\gamma\, b\, D^2}{2}$; and, similarly, that between the vertical face, CE, of the water just under the wave-front and the (as yet) stationary water on its right is $\frac{\gamma\, b\, d^2}{2}$.

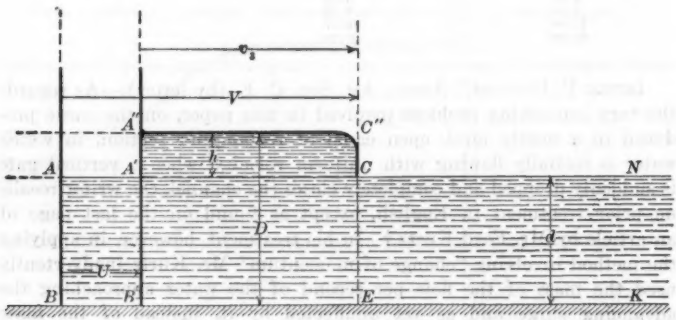

FIG. 5.

Let us now trace the motion for the first second of time. At the end of this second the plate is at $A'\,B'$, having moved a distance $\overline{AA'} = U$, the wave-front is at C, at a distance $\overline{AC} = V$, from AB, and the parallelopiped of water, $A''C''CEB'A'A''$ has a velocity, U (the water on the right being still at rest); while at the beginning of this second, the plate being at AB, this same mass of water formed the parallelopiped, $ACEBA$, and had a velocity of zero. The change of momentum brought about in this mass during the first second, therefore, is $\frac{\gamma\, V\, b\, d}{g}\,(U - 0)$, which is also the rate of change of momentum,

since the time concerned is a unit. Hence, equating the sum of the horizontal components of the external forces to the rate of change of momentum in a horizontal direction (neglecting friction on the bed), we have Mr. Church

$$\frac{\gamma\, b\, D^2}{2} - \frac{\gamma\, b\, d^2}{2} = \frac{\gamma\, V\, b\, d}{g}\, U \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Water being incompressible, we have also: volume, $AA'B'B$ = that of the horizontal "lamina", $A''C''CA'A''$; whence

$$Ud = (V - U)\,(D - d) \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

or,

$$UD = V(D - d) \quad \ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

that is, replacing $D - d$ by Flamant's symbol, h (height of wave), we may also write

$$Ud = (V - U)h \quad \ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

and

$$UD = Vh \quad \ldots\ldots\ldots\ldots\ldots\ldots (3c)$$

Eliminating U by means of Equations (2) and (3b), and writing h for $D - d$, we may solve for V, obtaining

$$V = \sqrt{g\left[d + \frac{3}{2}h + \frac{1}{2} \times \frac{h^2}{d}\right]} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

or, approximately, since the last term within the brackets is generally quite small compared with those preceding,

$$V = \sqrt{g\left[d + \frac{3}{2}h\right]} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4a)$$

or again, expanding $\left[1 + \frac{3}{2} \times \frac{h}{d}\right]^{\frac{1}{2}}$, and retaining only the first two terms of the converging series (that is, neglecting $\left(\frac{h}{d}\right)^2$ and higher powers as compared with the first two terms), we derive another approximate relation, *viz.*:

$$V = \left[1 + \frac{3}{4} \times \frac{h}{d}\right] \sqrt{g\, d} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4a)'$$

Flamant does not attempt to solve for the wave height, h, in terms of U and d, but is principally interested in the value of V, the velocity of wave propagation; but, if we substitute in Equation (2) the value of V derived from Equation (3a), there is obtained

$$\frac{D^2 - d^2}{2} = \frac{D\, d}{D - d} \times \frac{U^2}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

a cubic in D, if D (and finally h, $= D - d$) is sought; U and d being given.

Mr. Church.

Leaving Flamant's demonstration, it is noted that, relatively to the moving plate, the still water on the right of CE has a velocity toward the plate (call this velocity v) equal to U; and, similarly, that the velocity (call it v_3) of the wave-front, $C''CE$, relatively to the moving plate, is $A\,C$, that is, $V - U$, away from the plate. It follows, therefore, that in case the water in the open channel, with depth, d, has originally a velocity of v feet per second toward the left and the plate is suddenly dropped, so as to block completely the flow toward the left, and remains fixed in that position, the values of the wave-front velocity, v_3, and of D (or of wave height, h), become determinable by simply substituting v for U, and $v_3 + v$ for V, in the preceding equations. v_3, therefore, is the velocity of the wave-front, or surge, and D is the depth of the (now motionless) water between the plate and the wave front. This conception, by which the solution of the surge problem may be based on that of the plate advancing against still water, is introduced by the French engineer, Bazin, in a report (to be referred to later) on the experimental investigation of both cases.

In this way, then, we obtain for the problem of the surge wave dealt with by Mr. Johnson,

$$\frac{D^2 - d^2}{2} = \frac{D\,d}{D - d} \times \frac{v^2}{g} \qquad (6)$$

(which checks the author's Equation (1)), and

$$v_3 = \sqrt{g\left[d + \frac{3}{2}\,h + \frac{1}{2} \times \frac{h^2}{d}\right]} - v \qquad (7)$$

In these equations, and also in all subsequent formulas, the author's notation is used, with the addition of $h = D - d$. We may also set down for this case the approximate relations (see Equations (4*a*) and (4*a*)'):

$$v_3 = \sqrt{g\left[d + \frac{3}{2}\,h\right]} - v \qquad (8)$$

and

$$v_3 = \left[1 + \frac{3}{4} \times \frac{h}{d}\right]\sqrt{g\,d} - v \qquad (9)$$

As regards solving separately for the height of surge, h, or $D - d$, we may write $v_3 + v$ for V, and v for U, in Flamant's Equation (2), combine with Equation (9), and then solve the resulting quadratic; whence, if $v\sqrt{\frac{d}{g}}$ be denoted by k, there results

$$h = \frac{1}{4}\left[\sqrt{16\,d^2 + 8\,k\,d + 9\,k^2} + 3\,k - 4\,d\right] \qquad (10)$$

as a fair approximation when h is small compared with d.

Mr. Church.

We have, also, from Equation (3*b*)

$$vd = v_3 h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

In his report* to the French Academy of Sciences on an experimental investigation of the propagation of waves in open channels, Bazin gives the data and results of Bidone (1824) in the same field as well as Darcy's (1856). Bidone's experiments were performed on a very small scale, his channel being only about 2 ft. wide and about 40 ft. long in which to create and observe the wave phenomena; whereas Darcy and Bazin made use, not only of an experimental channel about 6.5 ft. wide and more than 1 000 ft. long, with depths of water of 2 ft. and less, but also of a straight reach of a navigation canal, some 3 000 ft. long and 30 ft. wide, with depths as great as 3 ft., as well as of a smaller basin 20 ft. wide.

Such being the fairly large scale on which the Darcy experiments were made, it has always seemed remarkable to the writer that Bidone's results should be quoted so frequently in American books on hydraulics, with little or no mention of Darcy's (in this field of wave motion, standing waves, etc.).

According to this report of Bazin's, Bidone derived the following relations from his experiments with surges going up stream and caused by the abrupt closing of a transverse gate in moving water, channel rectangular, *viz.*:

$$h = \frac{2\,d + h}{h} \times \frac{v^2}{2\,g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

which may be written $h = \frac{v^2}{2\,g}\left[\frac{1}{2} + \sqrt{\frac{4\,g\,d}{v^2} + \frac{1}{4}}\right] \ldots\ldots\ldots\ldots\ldots (12)$

and

$$v_3 = \frac{v\,d}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

As to the formulas based by Bazin on the Darcy experiments, let us first note that in 1844 J. Scott Russell presented, at the Fourteenth Meeting of the British Association for the Advancement of Science, an account of his interesting experiments on the "wave of translation" in still water. These were made on quite a small scale, in a channel of rectangular section, and led to the formula, $V = \sqrt{g(d + h)}$, for the velocity of the wave. (Compare with Flamant's Equation (4*a*).) This result was verified very satisfactorily by the Darcy experiments on the same phenomenon, these being made on a much larger scale. Bazin, therefore, adopted this formula, modified to suit the altered conditions, as a foundation for an expression for the velocity of wave propagation for the case now under discussion (sudden complete

* "Recherches Hydrauliques"; by Darcy and Bazin, Deuxième Partie, Paris, 1865.

Mr. Church. closing of a gate across a rectangular channel containing moving water). That is, he first writes

$$v_3 = \sqrt{g\,(d + h)} - v \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

and then eliminates h by the aid of the relation,

$$h\,v_3 = v\,d \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

see Equation (10*a*). The resulting cubic in v_3 can be factored, and yields one positive root, *viz.*:

$$v_3 = \sqrt{g\left(d + \frac{v^2}{4\,g}\right)} - \frac{v}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

But, experiment showing a somewhat larger value for h in terms of v_3 than as given by Equation (15), he modifies the algebraic relations on that basis and finally obtains, as fairly justified by experiment,

$$v_3 = \sqrt{\frac{v^2}{4} + g\,d} - \frac{2}{5}\,v \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

and, as an average,

$$h = \frac{1.2\,v\,d}{v_3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

As it may be of interest to compare the results obtained from these various formulas, let us take the data: $v = 4$ ft. per sec., and $d = 4$ ft., to find both v_3 and h (that is, $D - d$). The results are shown in Table 2.

TABLE 2.

Equation from which derived.	h, in feet.	v_3, in feet per second.

Bazin calls attention to an important fact which escaped the attention of Bidone: that the height of wave at the wave-front itself is somewhat greater than that of the portion of water behind. Bazin's formula seems to provide for this.

Paper No. 1382

THE PROPERTIES OF BALSA WOOD
(*Ochroma Lagopus*)*

By R. C. Carpenter, M. Am. Soc. C. E.

With Discussion by Messrs. A. P. Lundin and Leonard M. Cox.

Synopsis.

Balsa wood grows extensively in the Central American and northern South American States as a second-growth tree. It is the lightest wood known, so far as any evidence attainable is concerned. This paper shows the microscopical structure and also gives various tests of its transverse and compressive strength. The material is composed of very thin-walled cells, which are barrel-shaped, interlace with each other, and are almost devoid of woody fiber. These cells are filled with air, making a natural structure well adapted to prevent the transmission of heat, because of the particles of air imprisoned in the material without interconnecting fibers. Various tests of the insulating properties for resisting the flow of heat are given.

Balsa wood has been used quite extensively in the past as a buoyancy product for life preservers and in connection with the fenders of life-boats and rafts. Its life is short, under ordinary conditions, unless treated with antiseptic or preservative material. There is promise that it will have a field of usefulness, in the lines referred

* Presented at the meeting of June 7th, 1916.

to, which must make it of considerable interest to the engineer who requires either insulating material or buoyancy products.

Very little information is available respecting the wood of the balsa tree, which has recently been applied to several practical uses, and, as it possesses properties which make it valuable for many engineering purposes, the writer has thought it of sufficient interest to warrant the publication of the information which he has obtained regarding it. His interest in the wood was excited as the result of investigations as to its properties undertaken more than a year ago, and recently also by a visit to the Isthmus of Panama, where it grows extensively. The wood is remarkable: first, as to its lightness; second, as to its microscopical structure; third, as to the absence of woody fiber; fourth, as to its elastic character, in the sense of recovery from transverse deformation; and fifth, for its insulation qualities for heat. It is the lightest wood commercially useful, so far as the writer has been able to ascertain, and it has considerable structural strength, which makes it suitable for a fairly extensive use.

The Weight of Balsa Wood.

Balsa wood, when thoroughly dried, has a specific gravity of 0.11. For reference, Table 1* shows the relative weights of various woods. Until recently, Missouri cork wood, weighing 18.1 lb. per cu. ft., was supposed to be the lightest, but recent investigations indicate that balsa wood is much lighter, having a weight of 7.3 lb. per cu. ft. The ordinary commercial balsa wood is seldom perfectly dry, and, because of the moisture content, its weight, as appears from a number of investigations made by the writer, will usually be between 8 and 13 lb. per cu. ft. As will be seen from Table 1, however, it is much lighter than cork.

Cellular Structure of Balsa Wood.

The cellular structure of balsa wood, as exhibited under a microscope, differs from that of any other wood known to the writer. All engineers know that wood is made up of a series of interlacing cellular bodies of microscopic size which, when joined together, form fibers which extend both radially and longitudinally. These cellular fibers

* From the *Bulletin* of the Missouri Botanical Garden, August, 1915.

are interlaced, and, by their form and arrangement, give the wood its strength and physical properties. In ordinary woods the thickness of the walls of the cells is generally a considerable proportion of the diameter. The cells which are parallel to the axis of the tree are made up principally of woody fiber; those which extend in a radial direction usually have a cellulose structure with little woody fiber, and are defined as "medullary rays," or pith cells, because of their position and composition. The microscopic structure of all the woods involves, in addition, the existence of ducts or vessels scattered through the wood in a longitudinal direction; these serve as a circulatory system for the transmission of liquids and gases during the growth of the tree.

Figs. 1 to 6 are reproductions from micro-photographs of balsa (*Ochroma lagopus*). Figs. 1 and 2 show cross-sections, Figs. 3 and 4 radial sections, and Figs. 5 and 6 tangential or longitudinal sections. In these illustrations, the ducts or vessels are denoted by (*a*), the medullary rays by (*b*), and the barrel-shaped cells which constitute the longitudinal fiber, by (*c*).

To W. W. Rowlee, Professor of Botany in Cornell University, who assisted in the investigations, the writer is indebted for the micro-photographs and also for the following botanical description:

"*Gross Characteristics.*—In general appearance, balsa wood resembles basswood. As shown by the accompanying micro-photographs,

Figs. 1 to 6, its medullary or pith rays (*b*) are uniformly spaced, and are quite prominent in both the radial and cross-sections. In the radial sections, Figs. 3 and 4, they appear much as in maple or sycamore, as well as basswood, but lack the hardness and susceptibility to polish possessed by these woods. The ducts, pores, or vessels, shown at (*a*), are large and remote from each other, and occur singly, or in groups, in the strands between the pith rays (*b*).

"The lightness of the wood is one of its most striking features. This is due to the thinness of the walls of the elements. There is rather indistinct evidence of annual rings in the cross-section. In the specimens studied, the regular concentric rings, so characteristic of trees of temperate regions, do not show.

"*Minute Structure.*—The pith, or medullary ray cells (*b*) have normal position and form, but the cells are not elongated radially to so great an extent as is usually found in woods. The ducts (*a*) are large, with rather thin, pitted walls. Woody fibers of the ordinary sort seem to be absent in this wood, their place being taken by a cellulose tissue (*c*) very much like the thin-walled tissue of the pith and cortex of ordinary trees.

"The cells (*c*) making up this tissue are barrel-shaped, whereas woody fibers are taper-pointed and relatively much longer. The most remarkable thing about them, however, is their exceedingly thin, unlignified walls. A section of the tissue in question, examined under a microscope, would not be taken for wood, but rather thin-walled cells or 'parmchyma' from the pith or cortex of a stem. The only lignified part is the wall of the duct, and that is relatively weak.

"*Conclusions.*—

"1.—The gross structure of balsa wood is in appearance like basswood, poplar, or willow.

"2.—Its weight shows that it is fundamentally different from these.

"3.—Its minute anatomy is radically different from any wood known to the writer.

"4.—What correspond to the woody fibers, shown at (*c*), are not lignified. They are very thin-walled and soft.

"5.—The ducts or pores, shown at (*a*), are weakly lignified, and are pitted. They, however, constitute a very small proportion of the wood.

"6.—The pith rays, shown at (*b*), are also thin-walled and not lignified."

Microscopical Structure of White Pine (*Pinus Strobus*).—For the purpose of illustrating the interlacing fiber construction of ordinary woods, the writer presents micro-photographs of white pine, Figs. 7, 8, and 9, magnified about 100 diameters. Sections of the longitudinal cells are shown in Fig. 9 at *c c*; these have pointed ends, and are

many times longer than the field of the microscope. They have walls of woody fiber which are much thinner in pine than in hard woods like oak, but are thicker than in balsa. The cells constituting the medullary rays are shown at *d* in Figs. 7, 8, and 9; they are devoid of woody fiber, and are much shorter than the longitudinal cells, *c*, but they are longer than any of the cells in balsa wood. Pine has a very different cellular structure from balsa, as shown by the micro-photographs. In pine the longitudinal cell walls are composed principally of woody fiber, and the medullary ray cells of cellulose. The cells of the older wood, near the annual ring, have very thick walls in pine, as appears from Fig. 7. Evidently, the cellular structure of white pine is characteristic of a heavier wood, of less insulating capacity than balsa, and in that respect predicates the difference in physical tests and in insulating properties.

The Microscopical Structure of Cork Bark.—As illustrating a wood product, already in extensive use for heat insulating purposes, which has a cellular structure without interlacing fibers, attention is called to the micro-photographs of bark from the cork oak, *Quercus suber,* Figs. 10, 11, and 12. These interesting illustrations show that cork bark is composed of a series of thin-walled cells of small dimensions, without the interlacing fiber characteristics, as in the woods considered. The balsa wood, with respect to this feature, may be considered as intermediate between pine and cork bark. The value of cork and balsa for insulating purposes is evidently due to the close union of numerous closed cells filled with air. The deficiency of cork in structural strength is due to the absence of interlacing fibers which characterize balsa and other woods. It represents the extreme of cellular structure. The cork bark contains, interspersed between the cellular structure, a resinous deposit which is utilized, by aid of pressure and heat, in forming cork board, which is usually put on the market in blocks, 2 or 3 in. thick and from 2 to 6 ft. long, convenient for use as a lining in cold-storage or other structures. Cork is soft and readily compressible, and represents extreme characteristics possessed by balsa wood in a less degree.

The Strength of Balsa Wood.

Table 2 shows tests made under the writer's direction at Sibley College, Ithaca, N. Y., and also as reported by Professor Walter S. Leland, formerly of the Massachusetts Institute of Technology.

TABLE 2.—TRANSVERSE TESTS OF BALSA WOOD.

No.	Dimensions, in inches.	Modulus of rupture.	Deflection, in inches.	Quality.	Where made.
A	1¾ by 2½ by 20	2 880		Medium	Cornell.
B	1¾ " 2½ " 20	3 290		Clear	"
C	1¾ " ½ " 20		0.847	Clear	"
D	1¾ " ½ " 20		1.123	Clear	"
1	5 by 5 by 96	3 500	2	Clear	M. I. T.
2	1¾ " 4½ " 96	3 600	1 5/16	Poor	"
3	1¾ " 4½ " 96	2 900	1¼	Very poor	"
4	3 1/16 " 4⅝ " 96	3 300	2 9/32	Clear	"
5	1⅞ " 5½ " 96	3 207		Clear	"

Weight of Specimen *A*.....13.19 lb. per cu. ft.
" " " *B*.....10.05 " " " "
Average weight of Nos. 1-5.....13.2 " " " "

*Crushing and Compression Tests.**—Three specimens, each 1¾ by 2½ by 4 in., with a cross-section of 4.375 sq. in., gave an average of 2 488 lb. per sq. in. Another test of three specimens gave an average of 2 225 lb. per sq. in.

Three specimens, 1 by 1 by 3 in., crushed with loads of 2 210, 2 380, and 2 530 lb. per sq. in., respectively.

Two compression tests, of specimens 1 by 1 by 16 in., showed maximum loads of 1 860 and 1 980 lb., and net compression of 0.69 and 0.55 in., respectively.

One specimen, 5⅞ by 5⅞ by 23 25/32 in., crushed under a load of 40 900 lb., equivalent to 2 500 lb. per sq. in.; and one slightly smaller gave substantially the same strength per unit of section as reported by Professor Leland in Table 2.

Professor Leland states:

"The crushing strength seems to be very satisfactory for such wood—about one-half the strength of white pine or spruce.

"These tests show the modulus of rupture to be approximately one-half that of good spruce, and their uniformity clearly shows that the material may be relied on both for direct compression and transverse loads.

"It is very elastic material, and when the load was almost at the breaking point, the load on three of the beams was removed and the beams resumed their original shape.

"It is exceedingly interesting to note that it is practically impossible to split the wood by driving nails through it."

Fig. 13 shows a balsa wood plank supported on horses and carrying two men, the plank being 5½ in. wide, 1¾ in. thick, and 10 ft. 8 in.

* Except where otherwise noted, these tests were made at Cornell University.

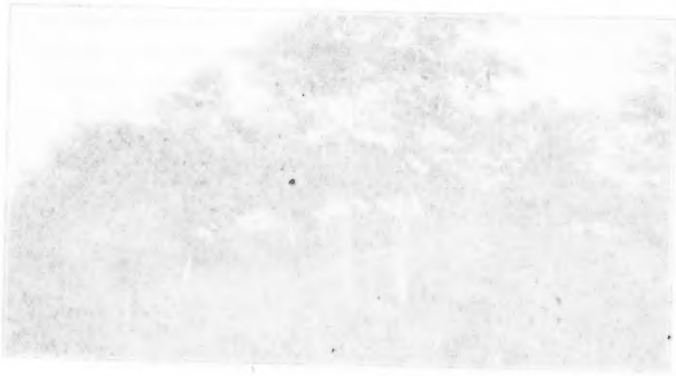

FIG. 13.—DEMONSTRATION OF THE ELASTIC DEFORMATION OF BALSA WOOD.

FIG. 14.—APPEARANCE OF YOUNG BALSA TREES, COSTA RICA.

between supports. The weights carried were 187 and 200 lb., respectively. The maximum deflection at the center was about 10 in.

The Habitat.

In a recent trip to the Isthmus of Panama the writer found balsa trees growing commonly in all the cleared spaces which were not under cultivation in the Canal Zone. Most of these trees were of small diameter, and evidently quite young, and in every instance they were found in the newly started jungle which has recently been allowed to grow over a goodly part of the Canal Zone since the canal has been completed. In some cases these trees were growing vigorously in the masses of material sliding into the canal. The tree is characterized by a large leaf, from 14 to 30 in. in greatest length, which has a form shown in Fig. 15, and by the peculiar seed pods which it bears when it reaches a larger size. Excellent evidence was obtained that the balsa tree grows very rapidly, and attains a diameter of from 12 to 14 in. at an age of 4 or 5 years. Rear-Admiral H. H. Rousseau, M. Am. Soc. C. E., now in charge of considerable construction work in the Canal Zone, told the writer that a balsa tree which was growing near his house at Culebra attained dimensions approximating 12 to 14 in. in diameter and from 40 to 60 ft. in height, in about 4 years. A considerable quantity of balsa of large size is to be found near the cleared plantations along the Chagres River, and in various other places near the Atlantic Coast and the banana plantations.

The result of an investigation of the forests of a number of tropical countries, by Mr. Herbert Paschke, undertaken for Capt. A. P. Lundin, indicates that balsa trees are found in considerable quantities in Honduras, Costa Rica, Colombia, and Jamaica, and there is abundant evidence that it grows vigorously in most of the tropical countries of South America. The report referred to indicates that the balsa or *ochroma* is entirely a second-growth wood, and is never found in the virgin forest, except as an isolated tree or two where clearing has occurred. The writer also learned, from his visit to the tropics, that forests composed of any one species do not exist in tropical countries, as they are found in the United States. Tropical trees always grow individually or by themselves, and very rarely in close proximity to other trees of the same species. This fact makes it necessary to spend considerable sums for transportation in gathering

any tropical timber, as great distances through the jungle have to be traversed in order to obtain the timber of a single tree. The general characteristics of the growing balsa tree are shown clearly in Fig. 14, reproduced from a photograph taken in Costa Rica.

Mr. Paschke states that balsa wood is known by different names in various American tropical countries, as follows:

In British Honduras.....“Moho”
In Guatemala.....“Lanillo” or “Moho”
In Spanish Honduras.....“Guano”
In Costa Rica.....“Balsa”
In Bocas del Toro.....“Moho”

Balsa wood, because of its lightness, has been known for a long time as a desirable material for floats, for supporting other material, and for rafts. Professor Gifford states that in the West Indies the natives use it for poles* “somewhat as the Chinese use the bamboo for shoulder poles, for all uses where a light, rather strong pole is needed.” So far as the writer could learn, balsa wood has no commercial value with people in the tropics who know about it, the general idea being that its lasting power is very slight, and that it warps and checks when exposed to the weather so as to be of little or no practical use.

Mr. W. F. Morgan, who recently made an investigation regarding the growth of balsa wood in Costa Rica, states that the natives are in the habit of cutting large balsa trees simply for the seed pods, which grow a woolly fiber suitable for pillows and mattresses. Fig. 16 shows a log of balsa wood, about 2 ft. in diameter, the tree having been cut down merely for the seed pods. Mr. Morgan also states that it has been the custom to use balsa wood in rafts of heavy timber for the purpose of securing buoyancy. At the end of a voyage, this wood is thrown away as having no commercial value.

It is thought that the first person to make any extended commercial use of balsa wood was Capt. A. P. Lundin, President of the Welin Marine Equipment Company, and formerly connected with the Pacific Mail Steamship Company. From his travels in tropical countries, Capt. Lundin knew of the extreme lightness of this wood, and its value as a buoyancy material in life preservers and life-boats was sug-

* von Schrenk.

FIG. 16.—BALSA WOOD LOG. TREES CUT FOR SEED PODS.

gested by its properties. When he undertook to apply the wood practically, however, he found that it was of little value because it absorbed moisture in great quantities, and also because it soon rotted, and also warped and checked when worked. He then undertook the discovery of some means of treating the wood which would render it water-proof and also prevent it from changing its shape. After testing nearly every method that had been suggested, Col. Marr's method of treating woods, which had been recently patented, was finally successful. In this method the wood is treated in a bath, of which the principal ingredient is paraffin, by a process which coats the interior cells without entirely clogging up the porous system. The paraffin remains as a coating or varnish over the interior cell walls, preventing the absorption of moisture and the ill effects as to change of volume and decay which would otherwise take place; it also prevents the bad effects of dry rot, which follows the use of any surface treatment for preserving wood of the balsa type.

The Marr process tends to drive out all water and make the wood water-proof; it improves the quality of being readily worked with tools, without material increase of weight. The treated balsa wood has been used extensively by the Welin Marine Equipment Company in the manufacture of life preservers, fenders for life-boats, and for structures requiring insulation from heat, as in the refrigerating compartments of vessels, and in ice boxes.

Transmission of Heat.

Specific Conductivity.—The Bureau of Standards, Washington, D. C., has determined the "specific conductivity", e, of balsa wood with the following results, expressed in British thermal units per hour, per square foot, per inch of thickness, per degree Fahrenheit of difference in temperature between the surfaces:

e for untreated balsa wood.	e for treated balsa wood.
0.394 B. t. u.	0.422 B. t. u.
0.352 "	0.350 "
0.403 "	0.424 "
	0.383 "

The lowest results obtained with both the treated and the untreated wood indicate a "specific conductivity" of 0.350. The higher results in other cases are to be attributed to imperfect specimens,

or to imperfect contact of the heat measuring devices. The Bureau of Standards uses electrical methods in measuring the heat supply and the temperature of the surfaces of the material, in order to eliminate all surface losses. The "specific conductivity" corresponds to e in the equation,

$$H = \frac{e}{x}(\theta - \theta'),$$

where x = the thickness, θ = the temperature of the entering surface, θ' = the temperature of the discharge surface, and H = the heat transmitted.

Heat Transmitted by Melting Ice.—Table 3 gives the results of the writer's investigation of heat transmission by determining the quantity of ice which melted in boxes made of balsa wood and other materials under known differences of temperature measured inside and outside. The results were reduced to British thermal units transmitted per square foot of mean surface between the outside and inside surfaces of each box, per degree of difference of temperature of the air inside and outside, per hour of time, which correspond to the "coefficient" of heat transmission, k, in the equation,

$$H = k\,(T - T'),$$

in which T = the temperature of the air on the entering side, and T' = the temperature of the air on the discharge side, the other symbols being as before stated. The coefficient, k, differs from the "specific conductivity", e, of the previous equation as it is dependent on the surface as well as the conduction capacity for heat transmission.

Relation Between "Specific Conductivity" and "Coefficient of Heat Transmission."—It is evident that the quantity of heat transmitted through any body is equal to that passing in succession each heat-resisting part. For example, if heat passes through a simple homogeneous body from a higher to a lower temperature, and from the air on one side to that on the other side, it must overcome: (1) the resistance of the entering surface, (2) the resistance of the material composing the body, and (3) the resistance of the surface from which it emerges. The surface resistances, (1) and (3), are overcome by radiation and convection, the interior resistance, (2), by conduction. The surface capacity for transmitting heat may be considered as equal

to the convection capacity plus the radiation capacity. The coefficients of radiation for most materials are known accurately, and may be calculated for different temperature conditions by the application of Stefan's or DuLong and Pettit's Law. The coefficients of convection are not known so accurately, but the values as stated by German engineers appear to give reliable results.

TABLE 3.—Heat Transmission Experiments in Sibley College. Tests Made by Melting Ice.

11	1	0.199	4.78	Balsa wood, treated.
....	1/16	0.660	15.82	Bare zinc, 1/16 in. thick.

k = coefficient of heat transmission per degree Fahrenheit of difference of temperature of air near the sides, per square foot, per inch of thickness, per hour;
$k' = 24\,k$.

The Bureau of Standards has given the name "specific conductivity" to the quantity of heat conducted, in British thermal units per square foot per hour, per inch of thickness, per degree of difference of temperature of the walls; and this term is used in this paper. This method does not consider surface losses, which vary with conditions. Engineering computations of heat transfer must usually be made by considering the temperatures of the air on the two sides, and require a knowledge of a coefficient of heat transfer per unit of area, per inch in thickness, per degree of difference of temperature of the air on each side, represented herein by k.

The following equations give the relation between "specific conduction", c, and "coefficient of heat transmission", k. They are rational,

and are recognized by French and German engineers as accurate. In the equations which follow,

H = heat transmitted per unit of surface per unit of time;

e = "specific conductivity", or heat transmitted per degree of difference of temperature of the sides of the material, per unit of time, per inch of thickness;

x = thickness;

a_1 = coefficient of surface flow entering the body;

a_0 = " " " " leaving the body;

k = coefficient of total heat transmission per degree of difference of air temperature, per inch of thickness;

$T - T'$ = difference of temperature of air on two sides;

$\theta - \theta'$ = " " " of material on two sides;

$t = T - \theta$ = drop of temperature entering the material;

$t' = \theta' - T'$ = drop of temperature leaving the material.

As the flow of heat is continuous, we have the following expressions, all equal to each other, as representing the flow through a single wall of homogeneous material without air space, per unit of surface, per unit of time:

Flow by conduction through interior.. $H = \frac{e}{x}(\theta - \theta')$ ....(1)

Surface flow entering..... $H = a_1 (T - \theta)$ ....(2)

Surface flow leaving..... $H = a_0 (\theta' - T')$ ...(3)

Total heat transmission..... $H = k (T - T')$ ...(4)

From these we can readily deduce

$$\frac{1}{k} = \frac{1}{a_1} + \frac{1}{a_0} + \frac{x}{e} \quad \text{.....(5)}$$

from which the relations between k and e can be computed, provided the values of a_1 and a_0 are known.

The foregoing equations apply to a single thickness without air space; but it is easy to calculate, by the same process of reasoning, the heat transmission through walls made up of various materials with

or without air spaces. In the case of a wall made up of two different materials with an air space between, we should find by calculation

$$\frac{1}{k} = \frac{1}{a_1} + \frac{x}{e} + \frac{1}{a_0} + \frac{1}{a_1'} + \frac{x}{e'} + \frac{1}{a_0'} \quad \ldots\ldots\ldots\ldots (6)$$

The temperature of the surface can be readily deduced by transposition in the equations given, thus, from Equation (2),

$$\theta = T - \frac{H}{a_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

The surface transmission coefficients have been worked out carefully for numerous cases by Rietschel and other German engineers. These are given by Kinealy,* in English units, as follows:

$$a = c + d + \frac{(40c + 30d)\,t}{1\,000} = c\,(1 + 0.004\,t) + d\,(1 + 0.003\,t)$$

$c = 0.82$ for still air;
$c = 1.03$ for air with moderate velocity;
$c = 1.23$ for air with high velocity.

Values of d.†

Brickwork	0.74	Iron, rusted	0.69
Mortar	0.74	Cast iron, new	0.65
Plaster of Paris	0.74	Sheet iron, polished	0.009
Stone masonry	0.74	Brass, polished	0.053
Wood	0.74	Copper "	0.033
Paper	0.78	Tin "	0.045
Glass, dry	0.60	Zinc "	0.049
Glass, wet surface	1.09	Zinc, dull	0.10

For thick walls and poor conductors, t is so small that it can be neglected. Rietschel gives values of t, for windows, as 36; for brickwork 5 in. thick, as 14; for brickwork 30 in. thick, as 5, for wooden doors, as 2.

Comparison of "Specific Conductivity", e, with "Coefficient of Heat Transmission", k.—The following computation is based on an assumed value of the "specific conductivity" ($e = 0.35$), as determined by the

* "Formulas and Tables for Heating", New York, David Williams Company.

† This table is the same as the Péclét table (see E. Péclét, "Traité de la Chaleur") for coefficients of radiation reduced to English units.

Bureau of Standards, a_0 and a_1 as computed from the preceding equations, and coefficients, which are as follows:

First, For a Single Wall Without Air Space.—

$$a_0 = a_1 = 0.82 + 0.74 + 0.01 = 1.57.$$

These values substituted in the general equation, give

$$\frac{1}{k} = \frac{1}{1.57} + \frac{1}{1.57} + \frac{x}{e}.$$

This, solved for $e = 0.35$ and for values of $x = 1$, 2, and 3, gives the following results:

"Specific conductivity."	Thickness, in inches.	"Coefficient of heat transmission."
$e = 0.35$	$x = 1$	$k = 0.242$
$e = 0.35$	$x = 2$	$k = 0.143$
$e = 0.35$	$x = 3$	$k = 0.1015$

Second, Single Balsa Wall, Ice in Zinc Box; Representing Test Results.—A box of balsa in still air, having thicknesses of 1, 2, and 3 in., respectively; melting ice confined in a dull zinc box, $\frac{1}{64}$ in. thick, the inside of which is in contact with the ice but separated from the balsa wood by an air space. These conditions correspond to those of the ice-melting test of which the results have been stated, and to which Equation (6) applies. For these conditions, $a_0 = 0$, and $\frac{x'}{e'}$ is so small that it is negligible.

Substituting numerical values, we have

$$a_1 = c + d = 0.82 + 0.10 + 0.92$$

$$\frac{1}{k} = \frac{1}{1.57} + \frac{1}{1.57} + \frac{x}{0.35} + \frac{1}{0.92}.$$

This, solved for different values, gives the following results:

"Specific conductivity."	Thickness in inches.	"Coefficient of heat transmission."
$e = 0.35$	$x = 1$	$k = 0.192$
$e = 0.35$	$x = 2$	$k = 0.124$
$e = 0.35$	$x = 3$	$k = 0.091$

Table 4 gives a comparison of the determinations of k by computation (assuming $e = 0.35$) and test.

TABLE 4.—Results with Balsa Wood Box.

"Coefficient of Heat Transmission," k.
"Specific Conduction" e.

Thickness of box, in inches.	By computation, assuming $e = 0.35$ (for 1 hour).	By Test, Melting Ice, in a Zinc Box, Inside Balsa.	
		k for 1 hour.	k' for 24 hours.
1	0.192	0.199	4.78
2	0.124	0.121	2.90
3	0.091	0.091	2.18

Engineers using insulating material for cold storage generally express the heat transmission coefficient on the basis of the heat, in British thermal units transmitted per degree Fahrenheit of difference in temperature of the air on the two sides, through material 1 in. in thickness, and for a period of 24 hours, which corresponds to k' in Table 4. The coefficient for 1-in. material is generally assumed as equal to twice the result obtained in a test of 2-in. material. In practice, only materials 2 and 3 in. in thickness are used, so that the coefficient obtained on such a basis, though not scientific, gives results which are fairly close. On such a basis, the "coefficient of heat transmitted" through balsa wood, per inch of thickness, computed from the Bureau of Standards tests, is 5.98; and, as determined by ice-melting experiments in Sibley College, is 5.80.

DISCUSSION

Mr. Lundin.

A. P. LUNDIN,* ESQ.—The speaker's attention was drawn to this wood many years ago, during voyages to tropical countries, *viz.*, Central and South America, Central Africa, and also India, in all of which the same species can be found; and he first remarked it when a number of natives came floating down a river on a raft made up of balsa logs. The logs were covered more or less with bark, and where this was chipped away there still remained the hard surface which is found on the outside of balsa logs, under the bark; the ends were covered with tar, or some waxy substance.

The natives, particularly in Central and South America, use such rafts to float their products to the sea coast, and seldom use them more than once, for one reason, because it would be difficult to bring the rafts up against the stream, and because the wood absorbs water very readily and the raft is more or less water-logged after arriving. Of course, in solid logs, with the ends closed up, the absorption is not so rapid as when balsa is freed from bark and cut up in planks.

Later, when engaged in the life-saving equipment business, it was brought to the speaker's attention that some crude attempts had been made to use balsa in life preservers. On taking over a boat shop in Long Island City, a quantity of balsa was found there, and, on inquiry as to its purpose, it was learned that experiments had been made with it in life-belt manufacture, but that the wood absorbed water so rapidly that the belts had to be made two or three times as large as the ordinary cork life-belt to assure the required buoyancy. Subsequently, chemical experts were put to work to devise methods for making the wood non-absorbent.

First, painting was tried, but, owing to the peculiar nature of the material, the paint was rapidly absorbed, and coating it over and over meant having just as much paint as wood, which added greatly to the weight. Then varnishing was tried, but, owing to the moisture left inside, the varnish cracked and blistered off.

Next, several mixtures of paraffin, asphaltum, gilsonite, etc., were tried, which gave a fairly good outside coating, penetrating about $\frac{1}{4}$ in. on the ends and about $\frac{1}{16}$ in. on the sides, and the problem was apparently solved. However, before long it became evident that, owing to the cellular structure of balsa, which is mostly pith, and the great quantity of moisture sealed up in the wood by the impervious surface treatment, dry-rot developed even sooner than in the untreated balsa.

* New York City.

Mr. Lundin.

Just at the time these difficulties became apparent, Col. Marr's water-proofing process was brought to the speaker's attention, and after numerous experiments with the new method, it was successfully and practically applied.

The United States Government tried out balsa life-preservers, life-buoys, etc., as compared with the cork articles, for a period of 49 days (24 hours per day), at the end of which period the cork preserver had lost all its buoyancy and the balsa preserver still retained the buoyancy stipulated in the Government requirements.

A few years ago, while working on the buoyant-material proposition, it was considered that, as balsa, owing to its peculiar structure, was so advantageous for use in buoyancy products, it might also be adaptable for insulation purposes, and accordingly experiments in that direction were begun. The first ice-box made of the new material was on the speaker's motor boat, and the results were surprising. All during the hot summer weather, ice was put in the box on Friday or Saturday, and on the following Friday or Saturday the temperature in the box would still be quite low and some ice was still left in the box.

Naturally, all first work in the line of balsa insulation was more or less crude, and the importance of scientific investigation was soon realized.

It was particularly fortunate that Professor Carpenter became interested in this material. The speaker well remembers that when he first spoke to him about this wood, and stated that it was all pith and no fiber, he and the gentlemen in his company looked very skeptical. However, he was sufficiently interested to visit the Welin plant, intending to remain there half an hour, but he spent practically a whole day, and when last seen on that occasion, he had all his pockets full of balsa, and he has been steadily devoted to the investigation ever since.

The speaker does not pretend to be an expert on insulation or non-conductivity, but looks at this material from a practical rather than a scientific viewpoint.

The principal feature in insulation material is, of course, that it must be a good non-conductor, but no doubt in the future engineers will also consider structural strength, and the possibility of making up complete homogeneous units will also be considered in judging the efficiency and value of insulating material, particularly where it is to be used in making ice-boxes and as insulation for buildings, in ships, and in railroad cars.

The principal consideration is a commercial one; in other words, good engineers always try to obtain the highest total efficiency, and commercial men want it and are willing to pay for it.

In shipping, for instance, it is known that almost any ship can be insured if built to certain requirements, such as Lloyds', and it

Mr. Lundin.

can be insured at the lowest rates (except, of course, in time of war). All cargo on such ships can also be insured at reasonable rates, except one class, and that is perishable food stuffs carried in refrigerator compartments, which are always carried at the shipper's or consignee's risk. Neither the steamship companies nor the insurance organizations will place insurance on such goods, except for the event of total disaster to the ship. Why? Not because the science of refrigeration has not kept pace with the science of naval architecture, but because of the fact that if a break-down occurs in the refrigerating machinery, the cargo will spoil, as the insulation is not reliable enough to keep the temperature sufficiently low until the machinery can be repaired and the system put to work again.

The speaker had an experience of this kind, many years ago, when on board a meat ship running from Australia to London. The machinery broke down while running through the Red Sea, and more than half the cargo spoiled in less than 24 hours.

A few years ago, in a meat market in Seattle, a new refrigerating plant, which had what might be called ordinary commercial insulating material, broke down, and before new parts could be obtained to replace the broken ones, and the machinery put in working order again, the damage to the meat in the market amounted to more than the cost of the refrigerating plant.

Therefore, when it comes to efficiency in insulation, there is still room for improvement. Perfection cannot be attained, but balsa wood will surely help to make insulation perfect, as it is not only a very efficient non-conductor, but has sufficient structural strength, and, through its physical properties, permits of constructing units with practically unbroken insulated surface walls.

A small ice-box, or pony refrigerator, made by the Welin Company, is of balsa wood, 2 in. thick, about 36 in. long, 21 in. wide, and 22 in. deep, and weighs about 30 lb. Such a box could not be made up of any other known insulating material. It is strong enough to stand severe jars, and a man could jump on it without straining it unduly. Of course, other woods will stand more rough usage than balsa, but, to meet this factor of additional strength, particularly on the surface, paneling made from the bark and waste of the wood is applied to the outside.

A small container, on the order of a thermos bottle, but in the form of a box made of 1-in. material, has a capacity of about 1 cu. ft. and weighs 6 lb. When going on an automobile trip, or something of that sort, the "lunch" can be placed in such a container—whether it is to be kept hot or cold. If it is wanted cold, a little ice should be put in to keep it so.

Butter has been sent all the way from Virginia to Southern California in such boxes, at an average outside temperature of 82°,

and the trip took 8 days, by the slowest route. Yet, when the boxes arrived at Los Angeles, the butter was still hard and frozen. Mr. Lundin.

Even if balsa had 30% less efficiency as a non-conductor, the speaker believes that it would meet a very common requirement for insulation, not satisfied by another material lacking in structural strength, which makes it possible to eliminate all leakage of heat through imperfect joints, or by use of cement or nails which may be classified as good conductors. Other insulating materials are almost entirely limited to use as a lining for a structure built of good conducting materials.

The speaker has a dream of perfect refrigerated transportation and conservation which may be of interest: It is growing more and more expensive to live in America and in many other countries. Food seems to be getting more scarce and more expensive all the time; heat in the winter and cold in the summer are rising in price, in short, the cost of every daily need is "going up."

Much of the increase in prices is due to waste, and, if this waste can be eliminated, it stands to reason that prices will go down. If foodstuffs could be transported, stored, and kept in first-class condition, not only the tremendous waste which exists to-day would be done away with, but food would be purer and would retain its full nutritive values, and this is very important, as there is no doubt that cold-storage food will have to be used to a large extent.

By instituting a continuous chain of proper and effective cold-storage and transportation facilities, which would insure the safe delivery of foodstuffs with a minimum of deterioration and a minimum of waste, some of the chief causes of the high cost of living would be removed, and this balsa insulation system could be spread, not only over the Western Continent, but all over the world. Foodstuffs would travel from producer to consumer in balsa containers—parcel post boxes, pony refrigerators, automobiles, railroad cars, ships—to be stored in balsa-walled storage warehouses, and, when delivered, would be put away in balsa house refrigerators.

The scope of this enterprise is very great. Insurance and guaranties would be furnished on such shipments, for with such highly improved methods to lessen the possible loss, insurance companies would find it to their interest to establish a standard specification on which basis the risk on perishable foodstuffs in transit could be covered.

The time is not far off when it will pay every architect to line his buildings with 1 or 2 in. of balsa wood, not only as an insulation lining but as a finish, instead of plaster and such coatings, which crack and fall down. Very attractive effects can be obtained with paneling in the interior of buildings.

There are a thousand and one uses for balsa, and in the future new ones will continually develop. Thanks and grateful acknowledg-

Mr. Lundin. ment are due to Professor Carpenter for the earnest scientific work he has done in investigating this wood.

Mr. Cox. LEONARD M. COX,* M. AM. SOC. C. E.—Although he can add nothing of professional value to the discussion of this excellent paper, the speaker feels a curious interest in the insulating properties of balsa wood. Some 15 years ago, it was his fortune to serve as Chief of Public Works at the Island of Guam, and among a number of more or less serious problems which confronted the pioneers of that day, was one which was never solved in an entirely satisfactory manner with the materials available. The cold storage room of the miniature ice plant served fairly well for caribou and American beef, but invariably caused the loss of fully half the mutton and poultry begged from the army transports on their monthly visits. From a first reading of the paper, it seemed at least possible that a very common Guam tree was akin to, if not identical with, the balsa tree, and that the remedy for our cold storage troubles had been near at hand though unrecognized. Personal notes consulted since the presentation of the paper before the Society establish the fact that the Guam tree, known locally as pago (*Hibiscus tiliaceus*), bears slight resemblance to the balsa tree, except as regards its comparative lightness and structure, as indicated by cut surfaces. Its weight per cubic foot is 24 lb.; it has considerable bending strength; is of about the color of Flemish oak; and rarely grows to a size exceeding 6 in. in diameter.

The reference in the paper to the Marr wood-preserving process also interests the speaker for the reason that while he was on duty at the Norfolk Navy Yard in April, 1914, a number of experimental timbers, running from 8 by 8 in. to 10 by 10 in., were impregnated with the Marr paraffin, in which there was incorporated finely divided silica. These pieces were suspended half in water and half in air, beneath one of the Yard wharves. At the same time six pieces, 4 by 6 in. and 4 by 4 in., were impregnated with the paraffin without silica, and buried to half their lengths in the ground. These test pieces were examined on July 15th, 1915, and found to be in excellent condition. They have also been examined during the latter part of June, 1916, and show no evidences of deterioration. The specimens which had been placed in water had a small quantity of shells and vegetable growth attached to their surfaces, all of which promptly fell off when the timbers were struck. On cutting into the wood, it was found that the interior was perfectly bright, and exhibited the distinctive red color of the process. The pieces in the ground show no signs of rot or age. Of course, tests on such a small scale cannot be considered determinative, and it is hoped that other engineers will give the Profession the benefit of any experience they may have had with this process.

Paper No. 1383

SUGGESTED CHANGES AND EXTENSION OF THE UNITED STATES WEATHER BUREAU SERVICE IN CALIFORNIA

REPORT OF A COMMITTEE OF THE SOUTHERN CALIFORNIA ASSOCIATION OF MEMBERS.*

BY GEORGE S. BINCKLEY, M. AM. SOC. C. E.,
AND CHARLES H. LEE, ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. N. C. GROVER, WILLIAM S. POST, CHARLES T. LEEDS, FRED. H. TIBBETTS, J. B. LIPPINCOTT, AND GEORGE S. BINCKLEY AND CHARLES H. LEE.

The Committee, appointed by the President of the Association on April 22d, 1914, to outline a plan for strengthening and extending the mountain climatological work of the United States Weather Bureau in California, so as to meet more widely and fully the needs of the industries and communities of the State relative to water supply, respectfully submits the following report.

Climatology is defined as that subdivision of meteorology which treats of the physical condition of the atmosphere during an extended period of time. Knowledge as to the climate of a place is obtained by a study of its continuous weather records—atmospheric pressure, temperature, rainfall, snowfall, direction and velocity of the wind, relative humidity, and evaporation—for a long period of years. The general relation of climatic factors to run-off and stream flow, as cause and effect, is so obvious, even to the layman, that no discussion is necessary.

* This report was presented to the Southern California Association of Members, Am. Soc. C. E., at its meeting of October 14th, 1914, and received the endorsement of the Association.

Throughout much of California and the Southwest the important streams have their sources in the mountain ranges bordering the valleys, and receive an almost negligible contribution from the valleys. In many districts arid valleys lie adjacent to mountain ranges receiving an annual precipitation of from 20 to 30 in. In such regions the gathering of climatic data, as a basis for the study of stream flow and water supply, should be carried on in mountains within the productive portions of drainage areas. This fact has been generally recognized throughout the West by irrigators, engineers, and some local officers of the United States Weather Bureau, ever since the commencement of irrigation development on a large scale.

The intimate relation which mountain precipitation, through stream flow, bears to the development and settlement of California is well shown by consideration of the communities and industries depending on reliable water supply. Agriculture, the most important industry of the State, to reach its greatest success, must generally be accompanied by irrigation. This has been fully demonstrated in Southern California and the San Joaquin Valley, and its truth is now recognized in the central and northern part of the State. The agriculturist, therefore, is fully as much interested in mountain climatology as related to water supply as he is in the atmospheric conditions immediately surrounding his crops. Hydro-electric power is rapidly taking a leading place throughout the State in manufacturing, transportation, and agriculture, as well as in supplying the physical needs of the inhabitants for light and heat. The reliability of the supply is largely dependent on stream flow, so that here, again, the average citizen is interested in mountain precipitation. Municipalities throughout the State depend for their very existence on mountain stream flow, for, if they do not derive their water supply directly from mountain run-off, as in the new Los Angeles Aqueduct system and the proposed Hetch Hetchy development, their water is pumped from underground reservoirs which, in turn, depend on precipitation and stream flow for replenishment. Finally, there is the subject of flood control and prevention which affects more or less the whole State and requires, to the fullest degree, definite and extended knowledge of mountain climatic data for its correct solution. In connection with this there is also the navigation of inland streams to be considered in the Great Central Valley of the State. The many

interests which would benefit by the collection, co-ordination, and publication of climatic data from the mountains are thus apparent.

The practical usefulness of climatic data is in forming a basis for the forecast of future stream flow variation. It is on the latter

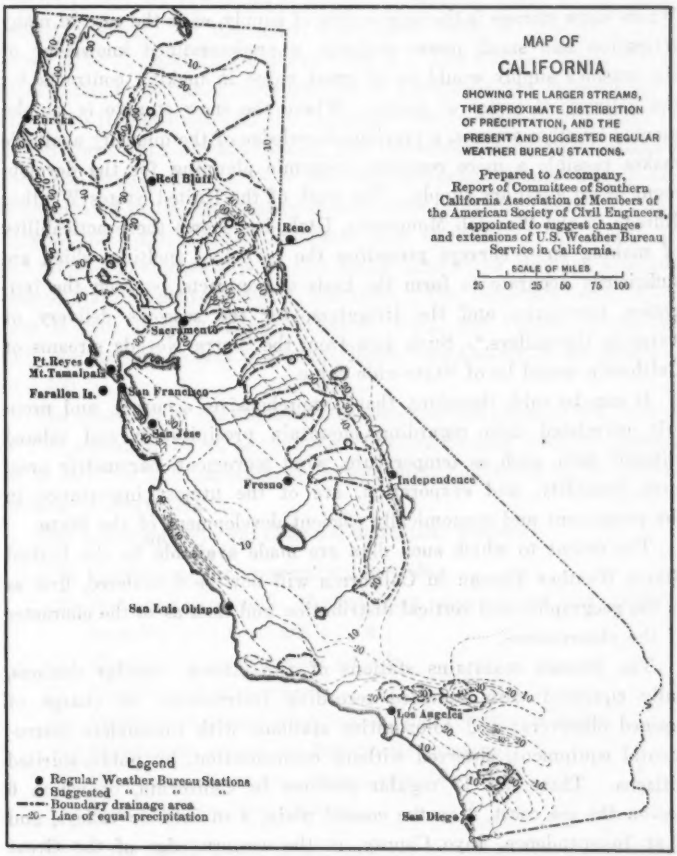

FIG. 1.

information that the magnitude or practicability of irrigation projects, hydro-electric power systems, municipal water developments, flood-protection works, or any other large engineering work, depending on

water supply or stream flow, is based. Such data have also great value in the design of engineering structures for the control of water, such as dams, spillways, head-works, bridges, levees, etc. There is still another field that is beginning to be recognized, namely, in the business management of projects depending wholly or in part on snow storage. Where snow storage is the only source of supply, as is the case in many irrigation and small power projects, a predetermined knowledge of the season's supply would be of great value in making contracts for the delivery of water or power. Where the snow storage is supplemented by other sources, a previous knowledge of the quantity available makes possible a more complete economic planning for the development of an auxiliary supply. The work of the United States Weather Bureau in the Wasatch Mountains, Utah, has shown the practicability of making snow surveys preceding the period of melting which are sufficiently accurate to form the basis of contracts, between the irrigation companies and the irrigators, for the season's delivery of water in the valleys.* Such data from the Sierra Nevada streams of California would be of State-wide value.

It can be said, therefore, that comprehensive, accurate, and properly correlated data regarding mountain precipitation and related climatic data, such as temperature, wind movement, barometric pressure, humidity, and evaporation, are of the utmost importance in the permanent and economically efficient development of the State.

The extent to which such data are made available by the United States Weather Bureau in California will now be considered, first as to the geographic and vertical distribution and then as to the character of the observations.

The Bureau maintains stations of two classes: regular stations, fully equipped with standard recording instruments, in charge of trained observers; and co-operative stations, with incomplete instrumental equipment, observed without compensation, by public-spirited citizens. There are 13 regular stations in California, of which 6 are on the sea coast, 2 on the coastal plain, 4 in interior valleys, and 1 at Independence, Inyo County, at the western edge of the Great Basin, in an arid region. There are no stations in mountainous regions, or in fact in any region from which the local precipitation and run-off will ever be an important source of water supply. There are listed in

* *Engineering News*, May 29th, 1913, p. 1110.

the California Section of the Climatological Service of the Weather Bureau, Annual Summary for 1913, 192 co-operative stations, of which 17 (9%) are within 25 miles of the coast; 104 (54%) are in interior valleys and foot-hills; 16 (8%) are in the Great Basin and desert; and 55 (29%) are in regions of broken topography where the elevation exceeds 2 000 ft. Of the latter, 4 are above 6 000 ft. elevation, 7 are above 5 000 ft., and 21 are above 4 000 ft. The vertical limits of the most copious mountain precipitation in California are between 4 000 and 6 000 ft. elevation. Of the 21 stations above 4 000 ft. elevation, 13 are in the Sierra Nevada Range, the remainder being well scattered over the State. Of the 13 in the Sierra Nevada Mountains, 10 are concentrated in the group of counties: Butte, Nevada, Placer, Plumas, Sierra, and Alpine, which comprise only one-fifth of the length of the range. The other 80% of this highly productive drainage area has only 3 stations above 4 000 ft. elevation. The important area tributary to San Joaquin, Kings, Kaweah, Kern, and Owens Rivers has only one station, namely at Bishop Creek, Inyo County, at an elevation of 8 500 ft.

The character of the climatological observations made by the Bureau will be considered: first, as to numerical climatic data obtained; second, as to location and exposure of instruments; and third, as to qualifications of observers.

The following data are obtained at regular stations:

(1) Continuous air temperature records;
(2) Wet and dry bulb thermometer observations for relative humidity at 5 A. M. and 5 P. M.;
(3) Continuous precipitation records;
(4) Clearness of atmosphere;
(5) Continuous record of direction and velocity of wind;
(6) Continuous record of barometric pressure;
(7) Occasional water evaporation records;
(8) Miscellaneous observations.

Such data are all useful to the engineer as well as the climatologist, and if obtained under representative local conditions are of great value.

At co-operative stations served by volunteer observers the following data are obtained:

(1) Daily readings of maximum and minimum thermometers;

(2) Total precipitation each 24 hours as caught and observed in standard 8-in. gauges (snow catch usually computed as equivalent water in ratio 10 to 1), depth of snowfall in 24 hours measured on the ground, total depth of snow on ground at time of observation;

(3) Miscellaneous phenomena, such as occurrence of frost, coronas, thunderstorms, tornadoes, auroras, general phenomena of climate, and general character of the day.

The method of snow measurement prescribed at co-operative stations is rather unsatisfactory, both in catching and in reducing to equivalent water. Great improvement would result from the substitution of snow bins for the 8-in. rain gauges. It is a simple matter to cut and weigh cores from the snow on a bin floor. Such a procedure would eliminate the present elements of inaccuracy: first, as to the effect on snow catch of wind currents about the mouth of the 8-in. gauge; second, as to judgment of observer in ascertaining snow depth; and third, in the use of the approximate ratios of fallen snow depth to equivalent water.

The location of instruments at regular stations in large towns and cities (9 out of 13 stations) is on the top of high office buildings. This has a tendency to detract from the practical value of temperature, precipitation, and wind observations. As regards temperature, it is a frequently observed fact in Southern California that on winter mornings, when low growing crops are suffering from freezing temperatures, the official record will show much milder temperature. This can be explained, first, from the fact that the record is kept in an upper and warmer air stratum, and second, by convection and radiation from the steam-heated building on which the thermometer shelter is placed. Then, as regards precipitation and wind, tall buildings cause vertical and cross-currents and eddies, and these obviously affect the precipitation catch as well as the anemometer record. At the regular stations in small towns and at isolated points the location is usually on the open ground, and far better exposures are secured. At co-operative stations the thermometer shelter and rain gauge are usually on the ground, but the gauge is often very poorly placed with respect to obstructing objects such as trees, outbuildings, or houses.

The observers at regular stations are trained men who usually make a life study of meteorology, and are accurate and systematic in their

work. They are essentially indoor office men, however, and are not encouraged by the Washington office to get out into the field, observe conditions on the ground, and keep in close touch with local conditions and the work of co-operative observers. There is no such body of active, efficient, field observers, for instance, as is maintained by the Water Resources Branch of the United States Geological Survey. As a result of this policy, the Weather Bureau has in many respects failed to meet the plain needs of western communities and provide data of uniform reliability.

The co-operative observers are private citizens, without training in systematic and accurate observation, who volunteer their services, and receive no compensation. They place and observe rain gauges without official supervision or instruction. Instruments are often not understood, or are out of repair, readings are occasionally omitted, and the general character of the observations is not by any means up to a first-class standard. The obvious remedy for these defects is frequent personal supervision by trained men from the district central office. Nevertheless, the co-operative observers have filled a great need, and the Weather Bureau is to be commended for its activity in finding public-spirited citizens who are willing to undertake such work, and for the rapidity with which these records are made available to the public, and the convenient manner in which they are presented.

Summarizing the work of the Weather Bureau in California, as regards the gathering of mountain climatic data, it appears:

First.—That no regular stations are maintained within the productive drainage area of any important stream of the State, nor are any systematic scientific studies made of the subject;

Second.—That of the 55 co-operative stations maintained in mountainous regions, 21 are above 4 000 ft. elevation, of which only 13 are in the Sierra Nevada Range, and 10 of the 13 are concentrated within about 20% of the area of the west slope;

Third.—That the co-operative stations are not equipped with instruments or men capable of gathering intelligently the data necessary for a comprehensive scientific study of mountain climatology as related to stream flow;

Fourth.—That the Weather Bureau does not maintain a corps of trained field observers capable of supplementing and keeping in touch with the co-operative observers;

Fifth.—That the placing of temperature, precipitation, and wind recording instruments on high buildings is practically without value to the agriculturist or engineer who attempts to use the data thus obtained.

In great contrast with the lack of regular stations in the mountains is their superabundance in the populated districts and along the coast. For example, within 50 miles of San Francisco there are 5 regular stations, San Francisco, San José, Point Reyes, Tamalpais, and Farallon. In the Great Valley there are 3 regular stations, Red Bluff, Sacramento, and Fresno; and along the south coast there are also 3 regular stations, San Luis Obispo, Los Angeles, and San Diego. At Independence, in a desert region possessing the characteristics of the Great Basin, there is maintained a fully equipped station which, because of its location, can have no practical value in solving the water supply problems of the State, unless supported by a station in the High Sierra to the west. Hence, there is evident a great inequality and inconsistency in the present distribution of regular Weather Bureau stations.

The Committee, after careful consideration of the facts as just stated and a study of the needs of the situation, presents the following outline as a working basis for extending the usefulness of the Weather Bureau:

I.—Establish at least 6 regular stations in the most productive mountain drainage areas, fully equipped with self-recording instruments and in charge of trained observers fitted for active outdoor field work. These stations should be, not only points at which climatologic data are collected, but also the headquarters for field observers having in charge local co-operative observers, and carrying on widely extended climatic surveys and special studies. If lack of funds prohibits the establishment of new stations, there is no reason why most of the existing stations could not be moved. Such action would be rather hard on certain of the Weather Bureau men, but would be of great benefit to the people of the State as a whole, and tend to distribute the benefits of the service more equitably. The locations of such stations suggested by the Committee are as follows:

1.—In the drainage area of McCloud or Lower Pitt Rivers;

2.—In the drainage area of the Feather or Yuba Rivers;

3.—In the drainage area of Stanislaus or Tuolumne Rivers;
4.—In the drainage area of San Joaquin or Kings Rivers;
5.—In the drainage area of Cache Creek above Clear Lake;
6.—In the drainage area of the Santa Ana River;
7.—In the drainage area of San Diego or San Luis Rey Rivers.

The conditions which should govern the location of these stations are: accessibility by wagon road or railroad from populated districts; accessibility in winter by skis or other means of travel for purposes of reading snow gauges and making snow surveys at points several days' journey distant; topographic features such as to insure the representative character of the station records; they should be in the zone of maximum rather than minimum precipitation for the drainage area; and, generally, should be where the facilities for the study of climatology as related to local water supply would be the best.

II.—Increase the number of co-operative stations in mountain areas now sparsely covered or not covered at all. In uninhabited areas, where neither mining settlements nor forest ranger stations are available, establish rain and snow gauges capable of holding a catch for an extended period.

III.—Organize a corps of trained field observers whose duties it will be to supervise personally the work of co-operative observers, and make special field studies, such as listed under IV.

IV.—Make special studies as follows, in as wide a territory as possible:

1.—Annual snow surveys in the drainage areas of Sierra Nevada streams;
2.—Snow movement subsequent to precipitation;
3.—The relation of temperature, forest trees, drifting, etc., to snow melting;
4.—The detailed relation between topography and precipitation;
5.—Water evaporation from lakes or reservoirs;
6.—Evaporation from snow;
7.—Establish, maintain, and observe snow and rain gauges at isolated points which can be reached only at long intervals;
8.—Any other investigations of practical value in the solution of the water-supply and flood-protection problems of the State.

The Committee has been frank in its criticism of the apparent fact that the principal meteorological observatories have generally been located rather more with reference to the comforts of a city than to secure the greatest efficiency and collect the most valuable data. This criticism, however, is not unfriendly. The staff of the Weather Bureau is uniformly courteous and obliging in furnishing whatever data are available; but, that these data have not a higher standard of reliability and greater practical value is due, the Committee believes, more to a lack of recognition of the great service that could and should be performed by the Weather Bureau, than to any reluctance on the part of those at its head to extend the scope and improve the value of its work.

In conclusion, the Committee does not hesitate to express the opinion that the questions involved in an improvement in the character of service rendered by the Weather Bureau may be discussed by engineers with the most complete freedom, and suggestions may be made without the slightest diffidence. Without in any way reflecting on the unquestioned scientific attainments of the officials of the Bureau, it is safe to say that the engineer who has to deal with the practical questions of water utilization is better qualified to indicate the source and character of meteorological data which will have the greatest real value, than the detached and abstract observer of meteorological phenomena.

The conclusions arrived at by the Committee are the result of mature consideration, and are now laid respectfully before the Association.

DISCUSSION

Mr. Grover.

N. C. GROVER,* M. AM. SOC. C. E. (by letter).—The writer is in hearty accord with the suggestions made in this report for rendering the climatological work of the United States Weather Bureau of greater practical value to the communities and industries of California. The desirability of collecting systematic records of temperature, precipitation, accumulation of snow and its equivalent in water, has long been recognized by Weather Bureau officials, as well as by others who need records of that character. The difficulty, as the writer understands it, however, is in devising instruments that will record correctly the phenomena desired, without daily attention, for it is unusual to be able to obtain reliable observers at high elevations in the mountains. Without such resident observers, or instruments that can be relied on to record the data without attention for several weeks, the cost of collecting the records becomes practically prohibitive. There is no doubt, however, that the officials of the Weather Bureau will gradually develop methods by which satisfactory records may be collected at high altitudes.

The following statements (pages 162 and 163) seem to be likely to be misinterpreted:

"In such regions the gathering of climatic data, as a basis for the study of stream flow and water supply, should be carried on in mountains within the productive portions of drainage areas.

* * * * * * * *

"The practical usefulness of climatic data is in forming a basis for the forecast of future stream flow variation. It is on the latter information that the magnitude or practicability of irrigation projects, hydro-electric power systems, municipal water developments, flood-protection works, or any other large engineering work, depending on water supply or stream flow, is based. Such data have also great value in the design of engineering structures for the control of water, such as dams, spillways, head-works, bridges, levees, etc."

Though the statements are not definite in this respect, the reader is left to infer that climatic data collected at properly located mountain stations will yield all the information as to water supply and its variations needed for the design of the important works mentioned. The dangers attending the use of estimates of water supply based on records of precipitation have been forcefully demonstrated by the many failures of hydraulic works of all classes. Such failures have been especially numerous in the irrigated areas of the West, and should serve as an object lesson not to be forgotten, but, unfortunately, many engineers appear never to have learned the lesson at all. Therefore, the inference that might be drawn from the report is particularly fal-

* Washington, D. C.

Mr. Grover. lacious, in view of the reliance that many engineers, both in the East and the West, continue to place on estimates based on records of precipitation, even though it has been demonstrated again and again that such estimates are not only not dependable, but positively misleading.

Mr. Post. WILLIAM S. POST,* ASSOC. M. AM. SOC. C. E. (by letter).—There is one feature of the Weather Bureau Service which only has to be stated to be recognized, namely, that this Bureau, as a matter of fact, has a monopoly of publication. It is, of course, a national organization, and perhaps cannot recognize local conditions to too great an extent, but the writer wishes to emphasize publication as an important matter, in addition to the recommendations of the Committee. There are numerous rainfall records in California, and presumably in other States, which are in the hands of private parties and cannot qualify as official. These records are of the utmost importance because they frequently go back as far as the early Seventies, and are fast disappearing with the dying out of the original observers. We have obtained or are maintaining some 60 stations alone in San Diego County which have no official means of publication. The writer would suggest that the Weather Bureau consent to publish all records in the State, in a volume devoted simply to rainfall, to be contributed from all known sources of information, the responsibility for the record being stated. In this way an extremely important source of information will be preserved.

In reference to this matter, the writer, alone and single-handed, some two years ago, attempted to convince the head of the Weather Bureau that the form of publication, in so far as it gives long lists of "normals", is a needless incumbrance of the present reports. To state it differently, what is required is not the mathematical interpretation of differential variations, etc., but a plain tabulation of the observed data. The first result of this, to the great relief of some engineers, would be a publication, 8½ by 11 in., which is a standard filing size, and the increase of the size of the type from a microscopic nonpareil to a good book type. It may be possible to convince a physical scientist that these normals have some significance, but most hydraulic engineers will agree that they are an unmitigated nuisance in the present publications.

The writer has suggested to one of the members of the Committee that, in case it is not possible to co-operate fully with the Weather Bureau in this matter of publication, the Society itself or the Local Association make permanent the present committee and undertake the publication of the meteorology of California, combining as contributors all those who can furnish any data.

* San Diego, Cal.

Mr. Post.

In hydraulic calculations, certain stations have become in the nature of base stations, and are very valuable for the purpose of restoring broken records or years of no record in the same region. For this reason it is a real loss to have a long-term station discontinued, merely, as it would seem, because the voluntary observer has moved and the Weather Bureau official has neither the money for traveling expenses to inspect and secure another observer, nor funds to hire a paid observer. The writer has recently expressed his regret at the discontinuance of the splendid record at Fort Wingate, in Arizona, to the extremely intelligent and competent Director of the Weather Bureau at Santa Fé, N. Mex., and was told that his hands were absolutely tied in the matter, that he could only secure a voluntary observer through correspondence, and had attempted to do so. That is a case where, because of the lack of an efficient field inspector, who could discover observers, a record which dates back to 1867 has been broken for about 3 years. Numerous other instances could be brought up.

The suggestion is also made that the Weather Bureau take up the study of local drainage areas for a few years, in order to determine the local shapes of the isohyetose lines once and for all in that area, and thereafter proceed with only one base station in that drainage area. The writer has succeeded in drawing such curves on certain drainage areas in Southern California by the establishment of some fifty rain gauges. In some cases there are voluntary observers and in others $1.00 per month is paid. About 15 gauges are examined by one hydrographer, who is also a good rider and can crank a machine. From a comparison of these curves, now that they have been established, it is obvious that a very considerable reduction in these stations can be made.

Mr. Leeds.

CHARLES T. LEEDS,* M. AM. SOC. C. E. (by letter).—The genesis of this paper was an address before the Southern California Association of Members, on April 8th, 1914, by Dr. Ford A. Carpenter, Local Forecaster of the U. S. Weather Bureau, which paper has since been published by the Weather Bureau under the title of "Flood Studies at Los Angeles". The discussion of this paper at that meeting developed the fact that the Weather Bureau, due to lack of funds and observers, is unable to establish as many co-operative stations as it would like to do. Dr. Carpenter stated that, if instruments could be furnished from other sources, he felt sure the Chief of the Weather Bureau and the Section Director at San Francisco would be glad, through the co-operation of the Forest Service, to assist in making the observations. He also stated that as soon as these extensions were authorized he would be glad to instruct the observers and collate all data.

Messrs. Binckley and Lee, therefore, were appointed as a Com-

* Los Angeles, Cal.

Mr. Leeds.

mittee, with the original purpose of investigating the possibility of obtaining the necessary rain gauges and of recommending advisable locations therefor. J. B. Lippincott, M. Am. Soc. C. E., then President of the Association, later instructed this Committee to broaden the scope of the report, as has been done.

The authors deserve commendation for the constructive recommendations which they have made. The Weather Bureau has been of great service in years past, and is now still further extending its usefulness. It is hoped that what criticisms have been made in the paper will be taken as meant only in a spirit of helpfulness.

Many who have not been in the Government service fail to appreciate the limitations imposed by legislative restrictions and lack of appropriations. These limitations should be borne in mind when considering such matters. It is hoped that public opinion may be so awakened as to lead Congress to remove these restrictions and provide adequate funds to permit the Weather Bureau to render to the country the greater service which it should be enabled to perform.

The authors have done well to state in their opening paragraph their purpose "to outline a plan for strengthening and extending the mountain climatological work of the United States Weather Bureau in California, so as to meet more widely and fully the needs of the industries and communities of the State relative to water supply". The paper deals only with this phase of the work of the U. S. Weather Bureau. It may lead to a better understanding of the whole matter to trace briefly here the development of the Weather Bureau, and state the duties now assigned to that Bureau by law.

The service now performed by the Weather Bureau was originally organized and carried on by the Signal Corps of the U. S. Army, and included only meteorological observations at military stations for the prediction of storms. To this was added in 1870 the duty of rendering reports relative to the stage of water in rivers. This service was primarily for the benefit of navigation on the ocean and the Great Lakes, and later included the interior districts and the great rivers. By Act of Congress, on October 1st, 1890, these duties were turned over to the present U. S. Weather Bureau of the Department of Agriculture. The duties then assigned to it were as follows:

"Forecasting the weather; the issue of storm warnings; the display of weather and flood signals for the benefit of agriculture, commerce and navigation; the gauging and reporting of rivers; the maintenance and operation of sea coast telegraph lines and the collection and transmission of marine intelligence for the benefit of commerce and navigation; the reporting of temperature and rainfall conditions for the cotton interests; the display of frost, cold wave and other signals; the distribution of meteorological information in the interest

of agriculture and commerce; the taking of such meteorological observations as may be necessary to establish and record the climatic conditions of the United States or are essential for the proper execution of the foregoing duties." Mr. Leeds.

It is regrettable that no mention is made by the authors of the storm warnings, sent out by the Weather Bureau, resulting in the prevention of untold disaster and loss of life. Nor is there any mention of the excellent system of frost prediction, such as has been developed in Southern California. Evaporation studies are urged (and wisely), but the implication is that none has been made. The authors have apparently overlooked the evaporation studies made by the Weather Bureau at Lake Tahoe and the Salton Sea. No mention is made of the careful and scientific studies, by the Aerial Research Department, of the upper air currents, made not long ago at Avalon, Cal.

The authors seem also to have overlooked the fact that the typical action of a storm center on this continent is to enter from the North Pacific, moving thence south-eastward and then north-eastward across the continent, and passing out into the Atlantic Ocean from New England or the St. Lawrence Basin. The most severe storms, however, enter through Southern California and proceed eastward and north-eastward across the continent. For the prediction of storms in the central and eastern part of the United States, therefore, it is essential that evidence of an atmospheric change or disturbance should be gathered as early in its course as practicable, and its direction and rate of progress must be carefully traced from place to place. It is doubtless to facilitate this purpose that so many regular stations are scattered along the coast. It must also be borne in mind that the regular weather bureau station, being a central distributing station for climatic information, must be situated so as to facilitate this collection and distribution of data. This of necessity requires that the regular stations shall be in centers of population.

The writer, as a hydraulic engineer, realizes fully the need of the information desired, and is thoroughly in sympathy with all extensions suggested. He is unable, however, to agree with the following statement on page 168:

"If lack of funds prohibits the establishment of new stations, there is no reason why most of the existing stations could not be moved. Such action would be rather hard on certain of the Weather Bureau men, but would be of great benefit to the people of the State as a whole, and tend to distribute the benefits of the service more equitably."

On the contrary, it is believed that this would benefit the hydraulic engineer and his clients of California at the expense of citizens of other classes, and even at the expense of hydraulic engineers in other parts of the country. What, for instance, would become of our navigation interests, if all regular stations were moved into the moun-

Mr. Leeds.

tains? What would become of the weather predictions, now made days ahead as a result of the early observations at regular coast stations? The Weather Bureau was created to serve the whole of the United States, and all branches of its work must be developed co-ordinately. The work of one station or locality cannot be developed with reference to the needs of that locality alone. Each section should be given the best service possible, consistent with equally good service to all other sections.

If, on page 170, line 9, there were inserted the words "by Congress and the general public", we would have a clearer statement of the truth, as the writer sees it, and it is not improbable that this was the thought in the minds of the authors.

The statement would then read as follows:

"The staff of the Weather Bureau is uniformly courteous and obliging in furnishing whatever data are available; but that these data have not a higher standard of reliability and greater practical value is due, the Committee believes, more to a lack of recognition, by Congress and the general public, of the great service that could and should be performed by the Weather Bureau, than to any reluctance on the part of those at its head to extend the scope and improve the value of its work."

As stated previously, the duties assigned by Congress to the Weather Bureau may be briefly summarized as making climatic observations and forecasting weather (particularly storms) for the benefit of agriculture, commerce, and navigation. This, broadly interpreted, would include all extensions recommended by the authors; but irrigation and hydro-electric development have proceeded so rapidly during recent years that the Weather Bureau has been unable, with the facilities provided by Congress, to keep pace with the requirements of the hydraulic engineer. Some extensions have been made, as already noted, but the attention of Congress should be directed to the need of facilities for still greater work. The Engineering Profession is probably in a better position to bring this to the attention of Congress than any other body of men. It is hoped that the present discussion will help to attain that end.

If the Weather Bureau has not sufficient funds to fulfill the duties assigned to it (as it is believed it has not), and if there are other allied duties which the Bureau should be directed and empowered to perform (as it is believed there are), then Congress should pass the necessary legislation to accomplish these ends.

The writer has had occasion, in connection with his work as a member of the Board of Engineers for Flood Control of Los Angeles County, to take up, with the present Chief of the U. S. Weather Bureau, the question of establishing additional co-operative stations in the different water-sheds in Los Angeles County. The Chief as well as

the local official and the Section Director of the Weather Bureau have expressed their willingness to co-operate to the extent of their ability. Mr. Leeds.

Another needed extension of the service of the Weather Bureau which has come to the notice of the writer is the lack of wind observations along the coast. This lack of information was brought home to him when he attempted to make a study of erosion along the California coast in recent years and the various factors affecting it, such as winds, tides, ocean currents, etc. So far as the writer knows, the only sea coast stations south of San Francisco for the observation of wind velocities and directions are at San Diego and San Pedro. The latter has been established only a short time, but will be of great service. The one at San Diego, being sheltered by Point Loma, is inadequate for showing wind velocities along the coast.

It is hoped that the Chief of the U. S. Weather Bureau will participate in the discussion of this paper and will describe fully the present work of the Bureau, its aims, its limitations, and how the Engineering Profession and the general public can assist the Bureau in making extensions of its present great service.

FRED. H. TIBBETTS,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer is particularly pleased with the constructive criticism contained in this report, and in the subsequent discussions. There is a strong and rapidly growing sentiment favoring the participation by organized engineers in the discussion of public problems. Engineers are the chief users of the data gathered by the Weather Bureau, and hence should be particularly qualified to support it and to urge the extension by Congress of its exceedingly useful work. Mr. Tibbetts.

Among the many important matters listed by the authors as pertaining to the Weather Bureau, the writer wishes to discuss the relation of the work of that Bureau to flood control and drainage problems, particularly in the Central Valley of California.

In the Sacramento Valley many important cities and towns, including the State Capital, as well as large areas of rich farming land, lie below the flood-plain of the river, and are partly protected by incomplete flood-control and drainage works. The accurate prediction of floods is a matter of the greatest importance. Every general flood has been attended by losses running from small amounts up to sums exceeding $5 000 000. The Weather Bureau deserves the greatest credit for predicting all the important floods, and for the prompt collection of the data issued in the daily river bulletins during the flood season, as well as for the uniform courtesy and devotion of its staff. Under the present organization, and with the limited funds available, however,

* San Francisco, Cal.

Mr. Tibbetts.

it is impossible to predict gauge heights with any great degree of accuracy, or more than 1 or 2 days in advance.

The typical winter storms of California are areas of low pressure which become detached from the much larger area which remains more or less permanently in the vicinity of the Aleutian Islands. These detached areas are swept eastward over the North Pacific Ocean, by the prevailing eastward drift of the atmosphere, until they impinge on the western shore of the continent. Their progress eastward is then determined by the direction from which they have advanced, and largely by local conditions. The storms are frequently broken up, or the direction of their movement is changed, by the high mountain ranges. The location of high-pressure areas at the time the storms strike the Coast is also important. A high-pressure area over Western Canada tends to deflect a storm southward; such an area over Central or Southern California tends to hold it to the north, and make it move parallel to the Canadian boundary. In general, these storms cannot be predicted on the Pacific Coast until they have actually arrived, and as they move ordinarily at a rate of from 10 to 15 miles per hour, storm warnings are too late to be of much value. Disastrous floods in a big river system such as the Sacramento occur only as the accumulative result of a number of such storms occurring in such quick succession that heavy precipitation continues for a number of days or weeks. If, when a heavy rainfall is occurring in the Sacramento Valley, it was possible to know that there was or was not, one, two, or more other storms a day or two off the coast, it would then be possible to predict with much greater accuracy, and for a much longer period in advance, the heavy and continued precipitation which causes high and prolonged flood stages in the river. For such work, two or three, or even one, station in the ocean from 500 to 1 000 miles off the western coast, would seem to the writer to be of as much value as all the other stations in California taken together. Such stations, if established in the ocean, would be not unlike some of the lightships off the coast. Only a limited outlay, and a limited number of observers would be necessary. The stations, of course, should be equipped with wireless, so that storms moving over the ocean could be reported immediately as to intensity, direction, and rate of movement. It is probable that, if regular reports were received from all ships equipped with wireless moving in the North Pacific, many of the severe storms could be accurately foretold a number of days before they arrived. One of the authors has suggested to the writer the occasional special use of naval vessels. The lines of ocean travel from Puget Sound to the Orient appear to go far enough north to make such observations of value.

Mr. Tibbetts.

The establishment of additional Weather Bureau Stations in the higher altitudes, as recommended by the authors, would also be of much use in predicting floods. The importance of the temperature of the air, particularly in the mountains, is almost equal to that of the precipitation. During the maximum discharge of the larger rivers, all but a negligible proportion of the water comes from the higher altitudes, the proportion probably being not unlike that of the annual run-off. Very few of the Weather Bureau Stations are high enough to indicate the conditions which give high rates of run-off. The fortunate fact that the Southern Pacific crosses the mountains at comparatively high altitudes, and is giving constant and valuable support to the Weather Bureau, is of great assistance. The effect of high temperatures in producing high rates of run-off has not received from engineers the study which it deserves, and to this can be largely attributed some of the apparently erratic results of the very wet January of 1916. During the heavy storms of that month the river at no time reached a dangerous stage, probably because the temperature in the mountains was so low that the precipitation piled up in temporary storage as snow. The highest stage of the river reached thus far in 1916, accompanied by a prolonged, heavy run-off (although at no time dangerous), occurred in response to comparatively light precipitation, accompanied by unusually warm weather during the first half of February.

Colusa Basin comprises the northeast corner of the flood basin of the Sacramento River. Back of the Reclamation Districts, which include more than 120 000 acres, there is a water-shed of about 1 600 sq. miles. About 950 sq. miles of this are occupied by comparatively level valleys and plains, and the remainder, producing most of the run-off, is composed of the bare foot-hills of the Coast Range rising to elevations of from 1 500 to 2 000 ft. The flood-control works now under construction are designed primarily to handle the run-off from these hills at a maximum rate of perhaps 25 000 sec-ft. There are only four (all co-operative) stations in this drainage area, all of which are below 200 ft. elevation. Rainfall records at these stations do not necessarily give an index of the run-off. The first flood of 1916, from January 3d to 8th, aggregating about 110 000 acre-ft., was accompanied by an unusually violent storm, averaging in the valley nearly 4 in. of precipitation in less than 24 hours. This indicated satisfactorily the crest of this flood 4 or 5 days in advance. The next and larger flood occurred between January 24th and 28th, and was not accompanied by any unusual precipitation of record at the stations in the water-shed mentioned previously. Had the stations been at the elevations at which the precipitation occurred, which caused this flood, they would probably have indicated its size and time of occurrence. This is inferred from the fact that this storm is shown clearly by the

Mr. Tibbetts.

rainfall records at Kennett, which although 120 miles farther north, and on quite a different water-shed, is at an elevation of 730 ft. The writer concludes that the vertical distribution of rainfall stations is far more important, from the standpoint of flood control, than their geographical location.

The work of the Weather Bureau in collecting and making public with amazing promptness the actual conditions all along the river, is of the greatest value. By 9 A. M. it is possible to ascertain, by telephoning to the Weather Bureau, the precipitation at each station for the preceding 24 hours, the stage of the river at 7 o'clock that morning, and its rise or fall within the last 24 hours. The mail service is so prompt that these records are usually received through the mail on the day that they are issued. The writer has only one suggestion here, and that is that more frequent observations during critical periods, or, better still, the use of automatic instruments giving a continuous record of the river stage, would be of the utmost interest and value. For example, at Red Bluff, at the head of the Sacramento Valley, the river sometimes rises or falls 15 ft. or more in 24 hours. The variation is almost as great at Colusa, near the head of the heavy flood-control works. The highest gauge at Colusa is ordinarily within from 1 to 3 ft. of that at Red Bluff, and from 18 to 36 hours later. Daily readings at Red Bluff may miss the crest of the flood by a number of feet, and render it that much more difficult to predict accurately the stage of water which will be reached on the levees from Stony Creek to the Feather River.

The writer's conclusions with regard to the work of the Weather Bureau, as it affects flood control and drainage, are:

Two observation stations in the ocean would be of more value, in predicting several days in advance the occurrence of heavy storms, than all the present stations in California combined. Regular information from vessels in the ocean might be of much assistance.

A more uniform vertical distribution of the Weather Bureau Stations, particularly in the higher altitudes, is desirable.

More importance and more study should be given by engineers to the effect of temperature in the mountains on the maximum rate of run-off.

The Weather Bureau has developed amazing efficiency and promptness in the collection and publication of river bulletins, and its local officials are uniformly courteous and desirous of making their work of the utmost usefulness, but the prediction of continued storms, and prolonged high-water stages, for a sufficient length of time to be of much use in flood-control work is physically impossible under present conditions on the Pacific Coast. The timely warnings issued, however, have been of inestimable value in saving life and property.

Mr. Lippincott.

J. B. LIPPINCOTT,* M. AM. SOC. C. E. (by letter).—The writer wishes to express his appreciation of this paper concerning the work of the U. S. Weather Bureau in California. This subject is of such interest to the hydraulic engineers of the West that this Committee (consisting of Mr. Binckley and Mr. Lee), representing the Southern California Association of Members of the American Society of Civil Engineers, was appointed for the purpose of reviewing this work. The report of the Committee was presented at a regular meeting of the Association, an evening was given to its discussion, a resolution of commendation was passed, and its publication by the Society was requested.

The work of the Weather Bureau and its predecessor, the United States Signal Service, in arid America has been of great value to engineers engaged in the study of the water problems of the West. The writer is especially indebted to the Service for much useful information. It is relatively an easy matter to maintain rain gauges, and an exceedingly difficult one to maintain stream gauging stations throughout a term of years. For this reason the engineers have had to rely largely on records of the Weather Bureau and Signal Service as a basis of their study of the available water supply for irrigation and water power.

There is a constant tendency for the older bureaus of the Federal Government to maintain themselves in the City of Washington without adequate field inspection, particularly of the far western country. It is not efficient, and in fact usually is very unintelligent for one to endeavor to direct, year after year, from a desk in the Capital, field operations on the far side of a continent. This lack of proper executive has not alone characterized the Weather Bureau for a number of years past, but many other departments of the Government. This habit was broken away from vigorously first by the Geological Survey, and then by the Forest Service and the Reclamation Service.

The Engineering Profession should use its influence in obtaining, if possible by co-operation with the Weather Bureau, an expansion and improvement of its work along lines that will be of greater value to this Profession.

In California there are two great hydrographic features: First, the Pacific Ocean with 850 miles of coast line lying to the west, from which all moisture is derived; and, second, the great Sierra Nevadas and Coast Ranges of mountains that are the condensers which collect the vapor from the clouds and put it into the streams. The rainfall in the valleys of California is small, ranging from 5 to 10 in. in the Great Central Valley, and from 10 to 15 in. along the coastal plains of Southern California. The desert rainfall to the east of the Sierra is

* Los Angeles, Cal.

Mr. Lippincott.

less than 5 in. annually. The precipitation on the mountain crests is enormously greater, the increase in depth of annual rainfall being at the rate of approximately 0.6 in. for each 100 ft. rise in elevation on the western slopes of the ranges up to some unknown limit for from 6 000 to 8 000 ft. The water, both for the irrigation supply and the development of power, comes from these high mountains, yet in California there are eleven regularly established Weather Bureau stations, all in the valleys and none in the higher mountains, the one possible exception being on Mt. Tamalpais, which is a branch of the San Francisco office on a foot-hill near that city.

Apparently, the original purpose of the Weather Bureau was to be of primary aid to shipping, which is of first importance. Seven of the eleven official weather stations in California are on the sea coast, and the others are in low valleys. In California there is great variation in the rainfall within short distances. For instance, at Fresno, in the San Joaquin Valley, the yearly rainfall is about 7 in., and 30 or 40 miles away the precipitation on the Sierra Nevadas is from 50 to 60 in., yet there are three official stations in the Central Valley and none on this main range. In a horticultural State which relies largely on irrigation for its success, and is greatly interested in flood problems and inland waterways, this would appear to be a condition to correct. The same argument applies in Southern California. If it is impossible to discontinue any one of the seven coast stations, it is essential that additional regular stations be established in the high mountain drainage basins. Apparently, the cost of maintaining one of the city offices would be enough to support two in a forest reserve where a cabin could be built and the records kept in an open field.

There are some voluntary observers in these mountain regions, but they are rarely at the higher elevations, or at points where maximum precipitation occurs. These voluntary observations are usually fragmentary, and are not an adequate substitute for a regular station.

Both off the west coast of Europe and the west coast of America the warm currents or streams of the ocean have a profound effect on the climatic conditions of the regions on which they impinge. It is quite possible that there is some variation or swing in these ocean streams from year to year. Navigators talk of open and closed winters off the coast of Northern Alaska, and there have been remarkable groups of wet and dry years in California. Storms originate on and travel easterly from the Pacific Ocean across the continent. So far as the writer knows, nothing has been done, in a broad and systematic way, to study the fluctuation in temperatures of the ocean water off the Pacific Coast. There are light-houses at short intervals from San Diego to Seattle, and others farther north. It would be a simple matter, not accompanied by serious expense, for the Weather Bureau to arrange with the Light-house Service for the taking of daily tem-

peratures of the water of the ocean, with a view of determining the possible relations between changes of water temperatures and cycles of wet and dry years. There may be no such relation, but it is a physical condition that might be studied to great advantage. The fishing industry of the Pacific Coast is growing to prime importance, and some believe that the schools of fish in their migrations are influenced by the ocean temperatures and that the season's catch is thus governed. Mr. Lippincott.

It is respectfully submitted that the work of the Weather Bureau could be substantially improved, also, at the localities where regular stations are now established. It is recognized by engineers, and also by the old Signal Service, that precipitation records should be taken on the level places rather than on pinnacles or near obstructions. The U. S. Weather Bureau has published a record of the rainfall in San Francisco extending back to 1849. This is a composite of observations made successively at six different stations. In 1892 the station was moved to the roof of the Mills Building. There is available a rainfall record, made by Mr. John Pettee, extending back to 1865-66. Although it is said that the gauge observed by Mr. Pettee was moved to different parts of the city several times, it is believed that it was always established near the ground, as distinctive from the roof of a building. For the 27 years prior to 1892 the Pettee record shows a reasonably close relation to that of the Weather Bureau, being an average of 97.2% of it. Subsequent to this date (when the Weather Bureau station was moved to the roof of the eleven-story Mills Building) there was a decided difference in the ratio of the two records. For the period, 1892-93 to 1900-01, the Pettee* record was 134.4% of the Weather Bureau record. This may not be taken as conclusive of the ratio of records maintained on the roofs of high office buildings and those observed near the ground, but it certainly indicates a wide difference in the results. Other examples could be referred to.†

Again, in such a country as California, where a change of a few degrees in temperature in the spring or winter is apt to mean the loss of the fruit crop by freezing, it is not satisfactory to have temperature taken on the roofs of high buildings. Occasionally, we are confronted with reports of frozen fruit, and see some ice in the streets, but we are assured by the official records of the Weather Bureau, taken at its regular station, that the minimum temperatures have been well above freezing. The reverse conditions exist in midsummer. When attention is called to this we are told to apply some factor in correction, but few persons outside the Service know what these factors are. In the writer's opinion, these observations should be taken on the surface of the ground, as it is not satisfactory to say that corrections

* *Transactions*, Am. Soc. C. E., Vol. LXI, p. 561.

† Fanning's "Hydraulics", p. 64.

Mr. Lippincott.

may be applied to adjust this great mass of observed data to normal conditions.

There are a number of voluntary meteorological observers, mostly in the valleys of California, who, year after year, send in records of rainfall and temperature, whose stations are not inspected, and who are not given personal instructions and encouragement as to the method of their work. Although some of the rain gauges are in good locations, others are not, and may be misleading. A distinction should be made in the records. The writer knew of two old gentlemen who kept a rainfall record for 20 years, from 1882 to 1902, at a place known as Second Gerrote, at an elevation of 2 714 ft. Their gauge consisted of three tin cans wired together and set out in the open lot to catch the rainfall. The depth of rain was read in each can with an ordinary foot-rule at the end of each storm, and the three observations were averaged and carefully recorded in a notebook. Such interest in a scientific subject should be encouraged by a visit and personal commendation, and the furnishing of adequate instruments for observation and instruction. The writer has never known of an extended field inspection trip being made by any officer of the Weather Bureau to these voluntary meteorological stations in California, the records from many of which have been continually published for years. It is probably not the lack of interest on the part of the local observers, but rather because of the "system" that is passed down from Washington.

A great deal of the work done by the men of the Weather Bureau is highly valuable and greatly appreciated. Their prediction of frosts is of greatest importance to the fruit growers of California; their prediction of storms is essential to the mariner. These gentlemen deserve full credit for the thoroughness of their organization, which is believed to be the most extensive meteorological department in the world, yet it is suggested that this service, good as it is, could be substantially improved, from the standpoint of the engineer, without the necessity of large additional outlays.

Messrs. Binckley and Lee.

GEORGE S. BINCKLEY,* M. AM. SOC. C. E., and CHARLES H. LEE,* ASSOC. M. AM. SOC. C. E. (by letter).—The Committee is gratified to find that the discussion of the paper has been constructive, and has covered all sides of the subject. The Committee has been actuated by a sincere desire to get at the truth and to be of constructive service. The discussions are indicative of similar motives.

Although none of the Weather Bureau officials has contributed formally to the discussion of the paper, which is a matter of regret, yet the members of the Committee have had informal personal discussions relative thereto with the present Chief of the Weather Bureau,

* Los Angeles, Cal.

Professor C. F. Marvin, and the official in charge at Los Angeles, Dr. Ford A. Carpenter. These gentlemen, though not always in accord with the conclusions reached, assisted in many ways in amplifying the Committee's information. The members of the Committee desire to express their appreciation of the helpful suggestions and the co-operative attitude of these gentlemen toward the work. Messrs. Binckley and Lee.

The Committee understands that, at the request of the Cleveland Association of Members, the Local Forecaster, Mr. William H. Alexander, of Cleveland, Ohio, addressed that organization on the subject of its paper. The Committee has not been furnished with a copy of this address, but was kindly loaned one by Dr. Ford A. Carpenter, from his office files.

Before proceeding further, the Committee wishes to make clear three points in which the paper may have misled those who read it.

First, the title and presentation of data might indicate that the Committee's findings and suggestions applied particularly, or even solely, to the State of California. This was far from the Committee's intention, however, as it is recognized that California enjoys its share —and a very full share—of the effort and funds at the disposal of the Weather Bureau, and that the local Weather Bureau officials are doing all in their power to obtain and distribute the information desired by the engineers of the State. The conditions set forth in the paper were regarded as typical of all the Western States, and also the Central, Eastern, and Southern States. California was chosen for detailed investigation because of the greater degree of first-hand knowledge thereof possessed by the Committee. That there is equal need for greater study of rainfall in the region east of the Rocky Mountains is indicated by the strong editorial which recently appeared in one of the leading engineering journals.*

Second, the Committee does not wish its advocacy of improvement in the mountain climatological work of the Weather Bureau to be interpreted as supporting the idea that precipitation data collected at properly located mountain stations will yield all the information as to water supply and its variations needed for the design of hydraulic structures and projects. On the contrary, the Committee is in full accord with Mr. N. C. Grover's statement, that stream-flow records furnish the most reliable data for this purpose. It is unfortunately the case, however, that the establishment of stream-gauging stations must be limited to one or two points on the larger streams, on account of the first cost and the upkeep. There are many projects, however, both public and private, which depend on the supply from the tributaries of large streams, or from small streams. There are also many short stream-gauging records which do not extend over years of deficient precipitation, and, without proper corrections, are likely to be

* *Engineering News*, August 17th, 1916, p. 321.

Messrs. Binckley and Lee.

as misleading as precipitation records unsupported by stream-flow data. To fill these deficiencies, precipitation records judiciously used in conjunction with the available stream-flow records are of great value, and afford the only adequate information, obtainable at reasonable cost, with which to supplement insufficient stream-flow records. It is toward the filling of this gap, which every hydraulic engineer in the West at least recognizes as a serious one, that the Committee's efforts are directed.

Third, the Committee's primary idea, in formulating its suggestions for improvement of the Weather Bureau Service, was not an increase in the volume of data collected, although that might be an incidental result, but an improvement in quality, to be obtained by a more studied choice of locations at which data are observed, and more intensive study and interpretation of the data thus obtained. For instance, in the matter of precipitation data, the hydraulic engineer wants to know: First, the average annual areal precipitation for all portions of a given drainage area, and the annual variations therefrom; and second, the monthly, daily, and hourly precipitation at one or more points in the area, depending on its size. As Mr. W. S. Post well suggests, this information can be obtained for Pacific Coast mountain drainage areas by determining the shape of the isohyetose lines from a few years records at a number of well-selected stations, after which one or two base stations would provide all the information needed. (This, of course, would not be sufficient for regions where a large proportion of the annual rainfall occurs in detached local storms covering limited areas.) By working out a progressive programme for a State along these lines, the total number of stations reporting at any one time could be kept constant, although the geographical location of stations would vary. As contrasted with such a programme, there is the present more or less haphazard distribution of rainfall stations, without regard to the ultimate usefulness of the record. The Committee recognizes the fact that to plan and execute such a programme would require much intelligent study and supervision by a practical and technically trained field man. The Committee wishes to emphasize again, however, that its efforts are actuated by a desire to see generally inaugurated a progressive, practical, co-operative, and broad handling of meteorological problems, to the end that these problems may be solved. Mechanically observing data for the sole purpose of tabulation and accumulation in the archives does not solve these problems, no matter how many stations are reporting.

The Committee wishes to correct an error which was inadvertently made in the paper. The number of co-operative stations in California reporting precipitation in 1913, as shown by the Annual Summary, is practically 300, instead of 192. Of these stations 8% are within

25 miles of the coast, 43% are in interior valleys and foot-hills, 7% are in the Great Basin and Desert, and 42% (instead of 29%) are in regions of broken topography where elevations exceed 2 000 ft. Of these, approximately 30 (instead of 21 as stated), were above 4 000 ft. Hence, out of the total, 10% can be considered as mountain stations. It should also be stated that subsequent to 1913 there have been published reports of snowfall data at from 40 to 50 stations in the Sierra Nevada Mountains. These data have been expressed in snow depths, however, and not in terms of equivalent water, so that they are of little use for water supply estimates. Messrs. Binckley and Lee.

The individual discussions will now be taken up in detail: Mr. Grover suggests, as the reason that so few records have been obtained by the Weather Bureau in mountainous regions, the difficulty in devising self-regulating instruments. The Committee believes that, due to the rapid development which has occurred in the West during the past few years, there will be found many more reliable observers in mountain areas than might be supposed. This has been the experience of the members of the Committee. The Committee respectfully suggests that, if the local officers of the Weather Bureau were given more assistants and were allowed to become intimately familiar with the mountain portions of their districts, many good observers could be found, in areas from which records are at present lacking, by obtaining the co-operation of such local residents and by the establishment of stations in the isolated areas in charge of trained men. As the Committee has suggested, it should be entirely feasible to obtain the desired records within a reasonable cost without waiting for the development of automatically recording instruments. The Committee has already commented on Mr. Grover's reference to the possible misinterpretation of its original report, and wishes here to express its appreciation to Mr. Grover for having brought out this matter with such clearness.

Mr. Post's discussion contains several very practical suggestions which are especially valuable, as they are drawn from his experience in making rainfall and run-off observations over a large area of mountain drainage. With regard to the publication of early records, of which, as Mr. Post states, many exist in California, it has been stated to the Committee, by the Chief of the Weather Bureau, that if a sufficient volume of such data be assembled and compiled by the Local Association, and presented to the Weather Bureau, the latter will undertake their publication in bulletin form under separate cover. The Committee is still engaged in gathering data of this character, and will appreciate any which members or others may be able to furnish.

Mr. Charles T. Leeds, brings out very clearly the diversity of work which has been assigned by law to the Weather Bureau, and the

Messrs. Binckley and Lee.

limitations under which it is working with respect to the needs of the water supply interests of the West. The force of his statements has been brought home to the Committee by its own investigations, and it fully agrees that the proper method of obtaining desired improvements is through Congressional action; and furthermore, that, "The Engineering Profession is probably in a better position to bring this to the attention of Congress than any other body of men." Mr. Leeds has done well to mention the many lines of special research work undertaken by the Weather Bureau. With regard to the evaporation studies made by that Bureau at Salton Sea about 6 years ago, however, attention is drawn to the fact that the data thus obtained have never been made available to the public. The Committee agrees with Mr. Leeds that stations for the collection and distribution of climatic information should be maintained in the centers of population. The Committee believes, however, that fully equipped (or regular) observation stations should be at a distance from buildings and other objects and influences which, in cities, cause abnormal conditions. The Committee suggests that both requirements could be met by establishing regular stations in Government-owned buildings and on Government-owned land, at the military and lighthouse reservations, of which many exist on the Pacific Coast, for example, the Presidio at San Francisco, Point Arguello near San Luis Obispo, Fort Rosecrans at San Diego, etc. There are military reservations adjoining practically all large coast centers of population, at which communication is fully as good as in the congested business district. The maintenance of such stations would, without doubt, be less than that of the expensive office quarters usually occupied by the Weather Bureau, and, in addition, the abnormal conditions existing on top of office buildings would be eliminated, without sacrificing the requirement of easy communication.

The Committee has not been unaware of the course traveled by the typical storm centers of this continent, as suggested by Mr. Leeds, but believes that, by reason of the large diameter of these storm centers, atmospheric changes occur no later on the west slopes of the mountain ranges of the Pacific Coast than they do on the Coast itself, and that records obtained from judiciously selected mountain stations would be of just as great value in forecasting weather conditions. In this matter, however, the Committee heartily agrees with Mr. Tibbetts, that

> "Two observation stations in the ocean would be of more value, in predicting several days in advance the occurrence of heavy storms, than all the present stations in California combined."

The Committee is indebted to Mr. Tibbetts for his valuable and instructive suggestions, as they represent the experience and viewpoint

of an engineer familiar with conditions in Central and Northern California. Messrs. Binckley and Lee.

In connection with Mr. Tibbett's suggestion, it is proper to call attention to the fact that, in the course of an oral discussion of the matter at a meeting of the Southern California Association of Members of the American Society of Civil Engineers, William Mulholland, M. Am. Soc. C. E., made the suggestion that naval vessels be used for the purpose of observing and reporting by wireless weather conditions off the coast. Though it seems to the Committee that the primary objects of the naval establishment would probably interfere with regular service of this character, such information as might be given, incident to the position of the vessel, would certainly be of high value. A much broader and more comprehensive service could be obtained very readily, however, by establishing the practice of communicating, through the Government wireless stations, with all shipping within range of the station, whether it be naval, coastwise, or deep-sea. The simple request of the American Consul at a foreign port would be quite sufficient, in a vast majority of cases, to insure the prompt attention of shipmasters to wireless inquiries from our Government stations, as to their position, direction of wind, barometric pressure, temperature, etc., and, with such a custom of communication established, the reciprocal advantage to the shipmasters would be correspondingly great. The utilization of such a source of meteorological data would involve practically no expense, would call for no additional plant or labor, and, the Committee believes, would result in a very great improvement in the advance with which conditions could be forecast, and in forecasts of far greater reliability.

Mr. Lippincott has well expressed the administrative policy of the Weather Bureau with respect to the West. The visit of the present Chief of the Weather Bureau to the Pacific Coast in 1915, and the recent extension of the mountain climatological work of that Bureau in Southern California, would indicate, however, that an effort is being made by the present administration to bring about a change for the better. The Committee can agree with Mr. Lippincott that the reason so few field inspection trips are made, by local officers of the Weather Bureau, is because of the "system". Before a local officer can leave his station for official business of any kind, no matter how trivial, he must go through a long process of correspondence with the Washington office. This sometimes consumes a month, and even then the authorization is frequently curtailed, and is often denied. There is small wonder, therefore, that co-operative records are often broken or discontinued. Such stations should be visited at least once a year, and at no pre-arranged time, in order to insure accurate results and the active co-operation of the observer.

Messrs. Binckley and Lee.

As a result of the discussions and the Committee's further investigation of the subject, it is believed that the following general conclusions are warranted:

1.—That the law creating the United States Weather Bureau prescribes a wide range of duties, among which the gathering of precipitation records is but incidental.

2.—That there is an urgent demand among engineers, throughout the United States, for more complete precipitation data throughout mountain drainage areas, to be used in conjunction with stream-flow data.

3.—That the present fiscal regulations, organization, and administrative policy of the Weather Bureau are not adapted to the task of gathering complete precipitation data of the character desired by engineers.

4.—That Congressional action should be sought, either to change the organization of the Weather Bureau, so that the desired result can be accomplished, or else that the duty of observing all factors affecting stream flow be turned over to the Water Resources Branch of the United States Geological Survey, with the appropriation of sufficient additional funds to carry on the work efficiently.

The Committee is continuing its studies in this matter, and its conclusions and suggestions, as just stated, are not to be considered final. The question of the establishment of a Bureau of Public Works, which shall co-ordinate all engineering activities of the Federal Government, and prevent the present duplication of effort, is believed worthy of careful study. Any further suggestions from the membership of the Society bearing on these matters will be greatly appreciated by the Committee.

Paper No. 1384

EARTH PRESSURES: A PRACTICAL COMPARISON OF THEORIES AND EXPERIMENTS.

By L. D. Cornish, M. Am. Soc. C. E.

With Discussion by Messrs. William Cain, G. M. Braune, F. N. Menefee, and L. D. Cornish.

Synopsis.

Of all structures which the engineer of to-day is required to design for conditions of static loading, there is probably none which is so irritating as the ordinary retaining wall. This, of course, is due to the lack of definite and correct data relative to the pressures exerted by the various kinds of earthy materials and to the variety of formulas which have been proposed for determining the amount and direction of the resultant earth pressure which acts on a retaining wall.

The writer has studied with a great deal of interest all the books and papers he could obtain concerning earth pressure theories, and the formulas or graphical analyses derived therefrom. Such study has been confined principally to a comparison of solutions based on the Rankine theory with those based on the sliding-wedge theory, and certain facts were developed which appear to discredit, in certain particulars, these commonly accepted theories. It is quite probable that other investigators have observed at least some of the same results, but, as the writer had never seen them discussed, he thought

the matter of sufficient importance to assemble the results of his studies in this brief paper.

Frequent reference will be made to the theories and formulas as either those of Rankine or Cain. A reference to Rankine is intended to relate, not only to the theory and formulas for the special cases as advanced by Rankine, but also to the solutions, based on his theory, covering all cases of inclination of a wall, as developed and published by Milo S. Ketchum* and M. A. Howe,† Members, Am. Soc. C. E. A reference to Cain relates to the solution by William Cain, M. Am. Soc. C. E., of the wedge theory as given in his paper‡ and in Ketchum's book.

Formulas to express the resultant earth pressure, as derived from the two theories, are similar, and in some cases identical; but the direction of the resultant force is different in all cases, except for a wall with vertical back and with the angle of surcharge equal to the angle of internal friction. These formulas, particularly those involving surcharge, are somewhat complicated, and it is impossible to grasp mentally their entire significance relative to the dimensions of a wall to resist the forces indicated by them. The writer has endeavored to show graphically the results obtained in actual wall design by the use of the different formulas and by values obtained in certain experiments, so that the points of interest may be discussed without resorting to mathematics. To accomplish this, and to avoid complications in equations, due to uneconomical distribution of masonry in the walls, all wall sections discussed will be triangular and designed as to width so that the resultant of the external forces shall cut a horizontal plane of the wall at the outer edge of the middle third.

Nomenclature.—The nomenclature used in Figs. 1 to 15, and discussion thereof is that used by Cain in his paper discussing Leygue's experiments, and, for the remainder of this paper, is the same as that used by Ketchum in his "Walls, Bins, and Grain Elevators". The differences are few and should cause no confusion, and the use

of both will facilitate quick comparison with the works of the authors mentioned.

h = vertical height of wall;

ch = " " " to center of pressure on AB, Fig. 1,

$c = \frac{1}{3}$;

ph = width of base of wall;

p = ratio of base to height;

e = weight of earth per cubic foot (Cain-Leygue);

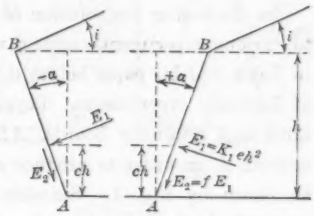

FIG. 1.

w = weight of earth per cubic foot (Ketchum);

W = total weight of earth per linear foot;

w_1 = weight of wall per cubic foot;

W_1 = total weight of wall per linear foot;

P = resultant earth pressure per linear foot of wall;

P_H and P_V = the horizontal and vertical components, respectively, of P;

$E_1 = K_1 eh^2$ = normal component of P (Cain-Leygue);

$E_2 = E_1 \tan. \phi^1$ = component of P parallel to back of wall (Cain-Leygue);

k = cohesion, in pounds per square foot (Cain-Leygue);

K_1 = coefficient of E_1 (Cain-Leygue);

i = inclination of surface of earth to horizontal (Cain-Leygue);

δ = inclination of surface of earth to horizontal (Ketchum);

α = angle between back of wall and the vertical, counted as positive or negative, as in Fig. 12* (Cain-Leygue);

ϕ = angle of repose (internal friction) of the earth fill;

ϕ^1 = angle of friction of the earth filling on the back of the wall;

* Reproduced herein as Fig. 1.

θ = angle between the back of the wall and a horizontal line extending into the fill = $90 + \alpha$;

$r = \dfrac{1 - \text{sin. } \phi}{1 + \text{sin. } \phi}$ = the Rankine ratio of horizontal to vertical earth pressures = k, as used by Ketchum.

In discussing his solution of the sliding-wedge theory, Cain refers to various experiments, among which are those made by Leygue* and in Table 3 of his paper before this Society.† Cain gives certain results of Leygue's experiments. Leygue's experiments were made with dry sand and retaining boards, *AB*, which could be rotated about the bottom, *A*, in order to produce any desired inclination to the vertical, as shown by Fig. 1. Suitable observations were taken and results obtained, from which the values of K_1, as given in the last column of Cain's Table 3, could be computed. The reader is referred to Cain's paper† for additional details.

The values of K_1 show the relative variation in the total normal thrust against walls under different conditions of loading and inclination of the back of the walls, but convey no immediate idea of the dimensions of the walls necessary to withstand such thrusts, and, after all, the dimensions are of most interest to the practical engineer or designer.

As a preliminary to the discussion of the formulas in common use, and to provide for subsequent comparison of designs based on theory with those based on experiments, retaining walls were designed to satisfy the experimental values of K_1, as given in the last column of Cain's Table 3. In designing the walls, the unit weight of earth, *e*, was assumed at 100 lb. per cu. ft., and the weight of wall, *w*, at 140 lb. per cu. ft. The resulting designs are shown by Figs. 2 to 8, and it may be noted that the values of *e* and *h* selected are such that $eh^2 = 10\,000$, and, consequently, the normal thrust, E_1, is 10 000 times K_1, or the significant figures of E_1 of the designs and of K_1 of Cain's Table 3 are the same.

The width of the base of the walls, *ph*, was computed from the equations for *p* shown for Figs. 2 to 15, which equations are condi-

* These experiments, with discussion thereon, may be found in *Annales des Ponts et Chaussées*, November, 1885.

tional on the resultant of all forces piercing the outer-third point, and the design was checked graphically as shown in the figures.

It may be noted that the required width of base steadily increases from Fig. 2 to Fig. 8. It is believed that any engineer, given these seven different cases at the same time and in a graphical form, would expect such a progressive increase, and that, in all cases, he would assert that an increase in the angle of surcharge, i, would require an increase in the width of the base. It is this point only which the foregoing discussion of Leygue's experiments is intended to emphasize for subsequent reference thereto.

In his paper, Cain showed that, in considering Leygue's experiments, the effect of cohesion should not be neglected, and, by graphical constructions and computations, he derives theoretical values of K_1, as given in the next to the last column of his Table 3 for assumed values of cohesion, k, as given in the third column of that table. It may be noted that the experimental values of K_1, as used in preparing Figs. 2 to 8, agree closely with the theoretical values, for k is equal to 1 lb. per sq. ft. Cohesion is usually neglected in practical designing, and, to show the effect of such neglect, walls, as shown by the smaller sections of Figs. 9 to 15, were designed for the theoretical values of K_1 corresponding to $k = 0$. All other assumptions were the same as those used for Figs. 2 to 8 and, therefore, the increase in section or base width is due entirely to the neglect of cohesion. The theoretical values of K_1 were derived by Cain from his theory; hence these are also the sections which result from the use of his formulas, and are marked for identification with his name. The base widths required for the same conditions were computed from the Rankine formulas, as modified by Ketchum or Howe, and the resulting sections are the larger ones marked Rankine in Figs. 9 to 15.

A study of these fourteen sections discloses three points of interest which warrant further investigation.

The first and most apparent point is the Rankine section of Fig. 12, which is smaller than the Rankine section of Fig. 11, although it is apparent by inspection that it should be larger on account of the 2:1 surcharge slope of the earth behind the wall. That it should be larger is proved by Leygue's experiments, as Fig. 5, with 2:1 surcharge, has a base 18% wider than Fig. 4, which has no surcharge. It

is also noted that the Rankine section, Fig. 13, for a 3:1 slope has a base about 1% less in width than the Rankine section of Fig. 11, which has no surcharge. These discrepancies between theory and experiment indicate that the formulas derived from the Rankine theory are erroneous, at least for certain conditions. This particular disagreement between theory on one side and reason and experiment on the other will doubtless be as surprising to many engineers as it was to the writer, and it will be discussed hereinafter in greater detail and for various conditions.

The second point of special interest is that, whereas the base of the experimental section, Fig. 4, is 30% wider than that of Fig. 3, yet the corresponding theoretical section, Fig. 11 (Cain), is 9% narrower than that of Fig. 10 (Cain). This indicates that, for walls with backs sloping toward the back-fill, the Cain and modified Rankine formulas give sections unnecessarily large. Walls of this kind are so unusual in practice that the writer, as yet, has made no further investigation of this case.

The third point is that the increase in base width of Figs. 14 and 15 (Cain) over that of Figs. 7 and 8 (Leygue) is much less than the corresponding increase for other comparable sections. This indicates that possibly the use of Cain's formulas for surcharged walls with a battered back results in sections only a little larger than for a case of no surcharge. Such is the case for walls with a vertical face and battered back, as will be shown hereinafter.

In order to put the formulas of Rankine and Cain in a comparable form, equations were deduced for p, the base width of triangular walls expressed as a percentage of the height. All the formulas for earth pressures as used are given by Ketchum,* and his nomenclature has been adopted for the following discussion in order to facilitate references.

The wall sections and equations are shown by Figs. 16 to 19 for the Rankine formulas, and by Figs. 20 to 23 for the Cain formulas. For the derivation of p, as shown, it is required that the resultant of all forces shall cut, and that the moments shall be taken about, the outer-third point of the base. The derivation of p for Figs. 16, 17, 18, and 20 is evident by inspection, as Figs. 17 and 20 require only the solving of the quadratic equation of moments.

* "The Design of Walls, Bins, and Grain Elevators."

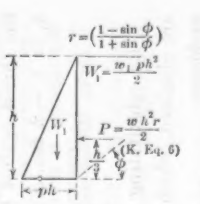

FIG. 16.

$\frac{w_1 p^2 h^2}{6}=\frac{w h^2 r}{6}$

whence $p=\sqrt{\frac{w r}{w_1}}$

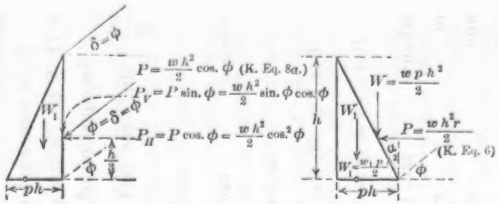

FIG. 17.

$\frac{w_1 p^2 h^2}{6}+\frac{2\,w\,p\,h^3}{6}\sin.\ \phi\cos.\ \phi-\frac{w\,h^3}{6}\cos.^2\phi=0$

whence

$p=-\frac{w}{w_1}\sin.\ \phi\cos.\ \phi+\sqrt{\left(\frac{w}{w_1}\sin.\ \phi\cos.\ \phi\right)^2+\frac{w}{w_1}\cos.^2\phi}$

FIG. 18.

$\frac{w p^2 h^3}{6}=\frac{w h^3 r}{6}$

whence

$p=\sqrt{r}$

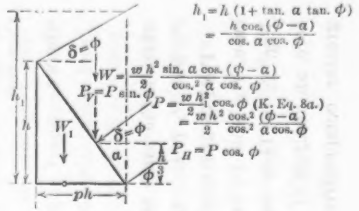

FIG. 19.

Let M = moment of a force, so that $M P_V$ may be read as the moment of force, P_V. Then $M W+M P_V-MP_H=0$, and, by substitution and reduction,

$p=\sqrt{\frac{1-\sin.^2\phi}{1+\sin.^2\phi}}$

Notes:- Figs. 16 to 19 accord with Rankine Theory.
" 20 to 23 " " Cain Theory.
Moments are taken about o, and it is required that the resultant of all forces pass through o.
The width of base: ph. are drawn to same scale for assumption that $\phi=33^\circ 41' 25''$.
(K. Eq.—) refers to the numbered equations in Ketchum's "Walls, Bins and Grain Elevators."

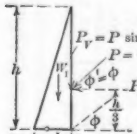

FIG. 20

$\frac{w_1 p^2 h^2}{6}+\frac{2\,w\,p\,h^2}{6}\frac{\sin.\phi\cos.\phi}{(1+\sin.\ \phi\sqrt{2})^2}-\frac{w\,h^2}{6}\frac{\cos.^2\phi}{(1+\sin.\ \phi\sqrt{2})^2}$

whence

$p=\frac{w}{w_1(1+\sin.\ \phi\sqrt{2})^2}\sin.\phi\cos.\phi+\sqrt{\left(\frac{w}{w_1(1+\sin.\ \phi\sqrt{2})^2}\sin.\phi\cos.\phi\right)^2+\frac{w}{w_1(1+\sin.\ \phi\sqrt{2})^2}\cos.^2\phi}$

FIG. 21.

This figure and equations are identical with those for Fig. 17.

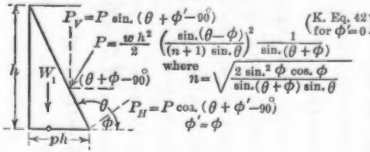

FIG. 22.

Similarly as for Fig. 19 $MP_V-MP_H=0$ whence it may be shown that $p=\sqrt{r}$ or the same as for Fig. 18

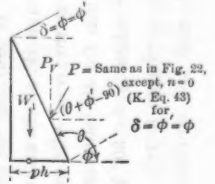

FIG. 23.

Similarly as for Fig. 22 it may be shown that $p=\sqrt{r}$

For Fig. 19, the earth thrust, P, against the wall is the same as the thrust against the vertical plane, bc, of height, h_1. The height,

$$h_1 = h + h \text{ tan. } \alpha \text{ tan. } \phi$$

$$= h \frac{(\text{cos. } \phi \text{ cos. } \alpha + \text{sin. } \phi \text{ sin. } \alpha)}{\text{cos. } \phi \text{ cos. } \alpha} = \frac{h \text{ cos. } (\phi - \alpha)}{\text{cos. } \phi \text{ cos. } \alpha}.$$

By substituting this value of h_1, the equations shown on Fig. 19 are obtained, which equations are in a convenient form for practical problems.

It is somewhat easier to derive p by substituting for h_1 its value, $h\ (1 + \text{tan. } \alpha \text{ tan. } \phi)$.

The equation of moments now becomes,

$$\frac{wh^3}{6}\Big[\text{sin. } \phi \text{ cos. } \phi\ (1 + \text{tan. } \alpha \text{ tan. } \phi)^2 \text{ tan. } \alpha + (1 + \text{tan. } \alpha \text{ tan. } \phi) \text{ tan.}^2 \alpha$$

$$- \text{cos.}^2 \phi\ (1 + \text{tan. } \alpha \text{ tan. } \phi)^2\Big] = 0;$$

whence $$\text{tan.}^2 \alpha\ (1 + \text{sin.}^2 \phi) - \text{cos.}^2 \phi = 0;$$

$$\text{and tan. } \alpha = \sqrt{\frac{1 - \text{sin.}^2 \phi}{1 + \text{sin.}^2 \phi}} = p.$$

For Fig. 22, the equation of moments is,

$$P \text{ sin. } (\theta + \phi - 90) \frac{h \text{ tan. } (\theta - 90)}{3} = P \text{ cos. } (\theta + \phi - 90) \frac{h}{3};$$

whence $$\text{tan. } (\theta - 90) = \text{cot. } (\theta + \phi - 90) = p;$$

or $$\text{cot. } \theta = \text{tan. } (\theta + \phi);$$

and $$\text{cot. } \theta - \text{tan. } \theta - 2 \text{ tan. } \phi = 0;$$

but, $$\text{cot. } \theta = -p;$$

therefore, $$p^2 + 2p \text{ tan. } \phi - 1 = 0;$$

whence, $$p = -\text{tan. } \phi + \sqrt{\text{tan.}^2 \phi + 1}$$

$$= \sqrt{\frac{1 - \text{sin. } \phi}{1 + \text{sin. } \phi}} = \sqrt{r},$$

which is the same as for Rankine Fig. 18. It also may be shown that P_H and P_V (Cain) are equal in amount to P and W, as shown in Fig. 18.

For Fig. 23 it may be shown in a similar way that $p = \sqrt{r}$, but, in this case, P_H and P_V are greater in amount than for the similar forces of Fig. 22. (They are four times as great when $\phi = 30°$.) Therefore, an analysis of Fig. 23 shows that the surcharge merely produces greater compressive stresses in the wall, and the equations for p

indicate that surcharging a wall does not increase its tendency to overturn so long as the unit compression stress remains within safe limits. Such an indication is so contrary to one's preconceived ideas of the effect of surcharge that the theory from which it results can scarcely be accepted until it is substantiated by experimental proof.

It may be noted that for Figs. 18, 19, 22, and 23, the equations for p show that the width of the base is independent of the weight of either the wall or the back-fill.

The equations for Figs. 16 and 17 give identical values of p for $\frac{w}{w_1} = \frac{100}{140}$ and $\phi = 0°$, $30°$, or $90°$; but p for Fig. 17 is the lesser for values of ϕ between $30°$ and $90°$ and greater for values less than $30°$, although the difference is not marked, as will be shown hereinafter. The narrow base resulting from the Rankine surcharge formula is due to the assumption that the resultant earth thrust is parallel to the inclined surface, as this assumption introduces a vertical component which produces a resisting moment sufficient to balance the excess overturning moment due to the surcharge. This virtually means the assumption of frictional resistance on the back of the wall, an assumption which Cain makes for all cases in his solution of the sliding-wedge theory.

The figures and equations for p on Figs. 16 to 23 show inadequately the inconsistencies of both theories when applied to various cases, but they show that neither theory gives results for surcharged walls which accord with the inference drawn from wall failures or from the experiments of Leygue, namely, that for any type of wall, if the surcharge is increased, the section must also be increased, provided the walls must satisfy the requirement that the resultant shall cut the outer-third point, or any other common point within the base.

The difference between the cases shown by Figs 16 to 23 is shown more clearly by Fig. 24, on which the p curves are plotted with reference to the rectangular co-ordinates, ϕ and p. The reference numbers on the curves refer to Figs. 16 to 23. The equations of the curves are either shown or reference is made to Figs. 16 to 23 on which they may be found, and, for all equations including the weight of the wall and the earth, it was assumed that $\frac{w}{w_1} = \frac{100}{140}$.

Curves 1 to 8 of Fig. 24 show the differences between the Rankine and Cain formulas and also between the formulas for the extreme conditions of no surcharge and maximum surcharge, but give no indication of the peculiar results obtained by the Rankine formula for Fig. 12 which is so much smaller than the corresponding wall, Fig. 11, which is not surcharged. This, however, is shown by the curves, $2a$ and $2b$, in the equations for which ϕ is a constant and δ a variable between the limits, zero and ϕ. These curves indicate that

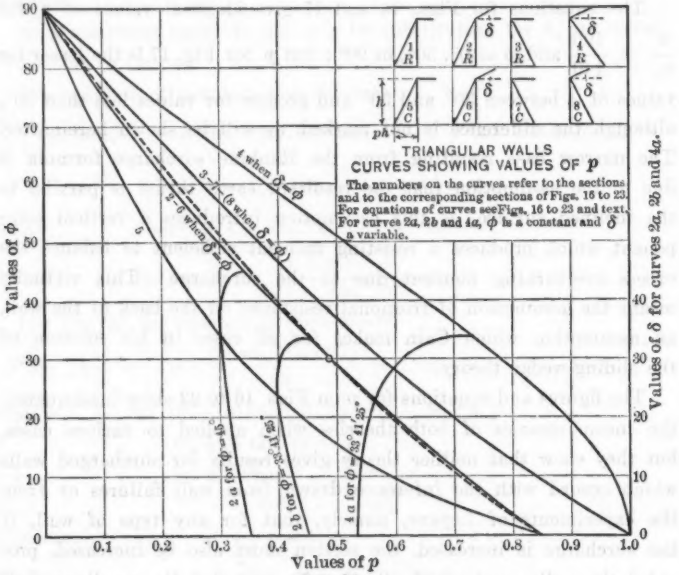

FIG. 24.

surcharging a wall increases its stability against overturning, and that a minimum base width is required when the angle of surcharge is only a few degrees less than that of repose or of maximum surcharge. Curve $4a$ has no minimum for finite values of δ, but is similar to the others in indicating a rapid decrease in p for small decreases in δ from its maximum value of ϕ.

The equations of Curves $2a$, $2b$, and $4a$ are as follows:

Let $A = \text{cos. } \delta \dfrac{\text{cos. } \delta - \sqrt{\text{cos.}^2 \delta - \text{cos.}^2 \phi}}{\text{cos. } \delta + \sqrt{\text{cos.}^2 \delta - \text{cos.}^2 \phi}}$, ($K.$ Equation 8), in

which ϕ is a constant; then for $2a$ and $2b$,

$$p = -\frac{w}{w_1} A \sin. \delta + \sqrt{\left(\frac{w}{w_1} A \sin. \delta\right)^2 + \frac{w}{w_1} A \cos. \delta};$$

and for Curve $4a$,

$$p = \sqrt{\frac{A \cos. \delta}{1 + A \tan. \delta \sin. \delta}}.$$

It is obvious that inferences, relative to surcharged earth pressure, to be drawn from Curves $2a$, $2b$, and $4a$, and from the similarity of Curves 1 and 2-6, are fallacious, and that, consequently, the Rankine theory—that the resultant earth thrust is parallel to the inclined surface of surcharge—is erroneous.

The writer has never been able to find or think of any good reason for assuming that the slope of surcharge should govern the slope of the resultant earth thrust for great depths, but will refrain from discussing it, as it is not the object of this paper to present a theoretical discussion, but to show, in as practical a way as the writer could devise, the results obtained from the application of the two principal existing theories.

DISCUSSION

Mr. Cain.

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—The author refers to Ketchum's "Walls and Bins" for the writer's theories of earth pressure. The statement there is incomplete, as the writer's theory relative to the "limiting plane" is not given in that book.† The reason for introducing this conception will be made plain from the following.

In Fig. 25, let $21O$ represent the free surface of an unlimited mass of earth, subjected to no force but its own weight, $2O$ being the line of greatest declivity, making the angle, i, with the horizontal. AO represents a vertical plane perpendicular to the plane of vertical section, $A2O$. Rankine has shown (Applied Mechanics, Arts. 125, 195) that the earth thrust, E, on the vertical plane, AO, acts parallel to $2O$, or to the free surface.

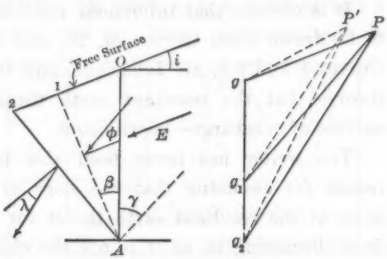

FIG. 25.

For the case supposed, there are two planes of rupture, shown by the dotted lines, which make angles, β and γ, with the vertical.‡ The thrust on the plane, $A1$, can be found by combining E, acting one-third of AO above A, with the weight of earth, $A1O$, the resultant making the angle, ϕ, with the normal to $A1$, as $A1$ is a plane of rupture. Similarly, the resultant thrust on a plane, $A2$, is found by combining E with the weight of earth, $A2O$. Suppose this resultant makes the angle, λ, with the normal to $A2$. We always have $\lambda < \phi$ (E. P., p. 38). The force diagram is shown to the right, Pg (to scale) being equal and parallel to E, gg_1 vertical and equal to the weight of $A1O$, and gg_2 vertical and equal to the weight of $A2O$. Thus, Pg_1 is the thrust on $A1$, making the angle, ϕ, with its normal, and Pg_2 is the thrust on $A2$, making the angle, λ, with its normal.

Now, in place of an unlimited mass of earth, as before, consider the earth limited by the retaining board, $A2$, which may likewise represent the inner face of a retaining wall extending to its left; and, for simplicity, take $\phi' = \phi$. It will now be shown that we cannot assume the thrust on the wall, $A2$, to make the angle, $\phi' = \phi$, with its normal and compute the thrust by the usual formulas involving wall friction.

* Chapel Hill, N. C.

† It is to be found in the writer's "Practical Designing of Retaining Walls" (D. Van Nostrand Co.), pp. 58–61, and in a more complete form in his "Earth Pressure, Retaining Walls and Bins", pp. 38–42, recently published by John Wiley and Sons. The latter book will be referred to in this discussion by the letters "E. P.".

‡ Formulas are derived in E. P., p. 102, for quickly computing these angles.

Mr. Cain.

In fact, in order that λ should equal ϕ, the graphical method (E. P., Fig. 10 and p. 38) shows that the thrust on AO must lie nearer the vertical in direction and have a less horizontal component than before. Therefore, on drawing g_2P', making the angle, ϕ, with the normal to $A2$, some line, $P'g$, lying above Pg, and having a less horizontal component than Pg, can be supposed to represent the thrust on AO. But, now, the resultant, $P'g_1$ on $A1$, lies nearer the vertical than Pg_1 and thus makes an angle greater than ϕ with the normal to $A1$. Hence, equilibrium is impossible. Therefore, λ cannot be assumed equal to ϕ, and the customary formulas cannot be used for finding the thrust on $A2$. The Rankine method is alone admissible, which consists in combining the thrust, $E = Pg$, acting parallel to the surface, with the weight of earth, $A2O = gg_2$, to find the true thrust, Pg_2, on the wall, $A\,2$. This acts at $\frac{1}{3}\,A\,2$ above A.

The plane of rupture, $A1$, is called the limiting plane. When the inner face of the wall, or retaining board, extends from A below it, the Rankine method just given must be used. If, however, the inner face of the wall or board extends from A above $A1$, then the usual (Cain) formulas apply.

For $\phi = 33° 41'$, the values of β and γ are as given in Table 1.

In Fig. 14, $i = 0°$ and $\alpha = 18° 26'$; the inner face of the wall lies above the limiting plane, as $18° 26' < 28° 10'$, and the Cain method is correctly given. In Fig. 15, however, the Cain and Rankine methods agree, and the sections should be identical, because, for $i = \phi$, $\beta = 0$,

TABLE 1.

i	β	γ
0	28° 10′	28° 10′
5°	26° 09′	30° 10′

and the limiting plane is vertical. The inner face of the wall lies below the limiting plane, and the Rankine method alone applies.

Similarly, the solution for Fig. 23 should be as indicated on Fig. 19, so that the remarks of the author, on pages 198-99, relative to Fig. 23, do not apply to the writer's section, which is identical with Fig. 19.

To summarize: The corrections just given refer only to Figs. 15 and 23, where the methods of Cain and Rankine are identical; so that, in Fig. 15, the Cain section should coincide with the Rankine section, and Fig. 23 should be replaced by Fig. 19.

Mr. Cain. The author has brought out the interesting fact that the Rankine section of Fig. 11, where the earth surface is horizontal, is actually larger than that of Fig. 12, where the earth surface is at the angle of repose. For very many years, the writer has pointed out the inaccuracy of the Rankine method when applied to retaining walls with vertical backs, the earth being level at top (see E. P., pages 18, 52, 277), and hopes that engineers will note the additional fact deduced by Mr. Cornish, showing the inconsistency of the Rankine method.

The author has reached certain conclusions, in comparing Figs. 2 to 8 with the corresponding set, Figs. 9 to 15, from which the writer is constrained to differ, simply because cohesion is included in the designs, Figs. 2 to 8, but is omitted in computing the sections, Figs. 9 to 15. The variation of p for the first set then offers no criterion for judging of what its variation should be for the second set.

The experimental values of K_1, of Leygue, were found by the use of rotating boards backed by sand, the boards being 0.656 ft. (say, 8 in.) in height. The writer found that, on account of the very small height, the influence of cohesion was very marked, though only the very small value of cohesion of about 1 lb. per sq. ft., was exerted. Further, it was found, as exhibited in Table 3,* that the theoretical values of K_1, for a cohesion of about 1 lb. per sq. ft., agreed very well with the experimental values; so that sections of retaining walls, based on the experimental values of K_1, should agree very closely with the sections found by theory for earth endowed with friction and a cohesion of 1 lb. per sq. ft., for walls 8 in. in height.

For walls 10 ft. high, a larger cohesion coefficient is required than 1 lb. per sq. ft., in order to give the experimental values of K_1 pertaining to the 8-in. walls, which the author has used. By using the construction, Fig. 11, of the paper just cited, it will be found, for earth weighing 100 lb. per cu. ft., level at top and deposited behind a vertical board, that the experimental value, $K_1 = 0.090$, corresponds to about 20 lb. per sq. ft. cohesion.

Figs. 2 to 8 can then be conceived to be theoretical designs for walls 10 ft. high, backed by earth weighing 100 lb. per cu. ft., with a cohesion of 20 lb. per sq. ft., and an angle of friction, $\phi = 33° 41'$, the masonry weighing 140 lb. per cu. ft., the theoretical and experimental values of K_1 being nearly the same. Now, the theoretical sections, Figs. 9 to 15 (Cain)—Fig. 15 being corrected as above—correspond to the same earth, but without cohesion. By reference to the paper cited,† it is seen, for the experimental walls examined, of sufficient height for cohesion to be negligible, that the experimental and theoretical values (Cain) of K_1 were practically identical; so that Figs. 9 to 15 can be

* "Experiments on Retaining Walls", etc., by the writer, *Transactions*, Am. Soc. C. E., Vol. LXXII (1911), p. 421.

† *Transactions*, Am. Soc. C. E., Vol. LXXII, pp. 407–413, 426.

regarded as walls designed for experimental values of K_1 for earth without cohesion. Mr. Cain.

Thus, Figs. 2 to 8, as well as Figs. 9 to 15 (Cain) can be regarded as sections designed for experimental values of K_1, the backing, in the first set, being of coherent earth, and in the second set, of non-coherent earth. If this is true, then both sets of sections are correct, and the author is unwarranted in his assumption that the variation of p in the first set offers any criterion for judging of what the variation should be for the second set. If these sections are regarded as experimental ones, as seems highly probable from the reasoning above, then the shortcomings of the Rankine sections, Figs. 11 and 12, are made evident by the comparison.

In the sections, Figs. 9 and 10 (Cain), the earth thrust has been assumed to make the angle, ϕ, with the normal to the wall. This assumption is nearly true where α is small (say, $\alpha < 10°$), but the investigations of Résal* lead to a definite formula for this obliquity, which the writer has adopted (E. P., p. 97), and which leads to a somewhat smaller value than ϕ, for the obliquity, for $\alpha = 18° 26'$. The sections, Figs. 9 and 10 (Cain), would thus be larger and would probably approach the Ketchum-Rankine sections. Experiments on model walls, from 6 to 10 ft. high, backed by clean sand, so that the influence of cohesion is negligible, are sadly needed, in order to check, or perhaps modify, theory, particularly with respect to leaning walls. In fact, it is known from experiment, that the surface of rupture is curved and not plane, so that the theory of earth pressure against retaining walls, which assumes a plane surface of rupture, is admittedly approximate, and experiments on large models will almost certainly modify its indications.† Since there is no approximation introduced in the Rankine formula for the thrust on a vertical plane in an unlimited mass of earth, its results should agree with experiment and one would naturally expect the results pertaining to Fig. 15 (Rankine) to be verified by experiment.

Two noted authors, Boussinesq and Résal, have endeavored to complete the Rankine theory by considering the modifications necessary for those cases where the full friction of earth on wall is exerted. For such cases, both authors regard the earth thrust on the wall as making the angle, ϕ, with the normal to the wall. The case where $\phi' < \phi$ is not considered by either. Both theories are very intricate, but the results are probably more correct than those pertaining to the ordinary

* Poussée des Terres", Vol. 1.

† The modification will doubtless be more pronounced for leaning walls than for vertical or battered ones; because, when the wall leans toward the earth filling, the wedge of rupture is much smaller than for the battered walls; hence, any error due to assuming a plane surface of rupture in place of the true, curved one, should be more pronounced for the leaning walls, since, for them, the percentage of error made in the assumed wedge of rupture is greater for the leaning than for the battered walls. Further, the direction of the thrust on a leaning wall, derived from Résal's assumptions, needs experimental verification.

Mr. Cain. sliding wedge hypothesis used by the writer. The numerical values of K in Table 2 may prove interesting.*

TABLE 2.—VALUES OF K.

Earth Surface Horizontal.

− 20°	"	"	0.236	0.235	0.234
− 25°	"	"	0.274	0.273	0.272

In Table 2, α is the angle made by the inner face of the wall with the vertical, + referring to walls leaning toward the earth, and − referring to battered walls, as in Fig. 1. The angle of friction $= \phi$, the weight of earth $= w$, in pounds per cubic foot, and the thrust on the wall of height, h, is, $E = K\ wh^2$. Its component, normal to the wall, is $E_1 = K_1\ wh^2$. The thrust, E, makes the angle, λ, with and above the normal to the wall; hence $E_1 = E \cos. \lambda$ and $K_1 = K \cos. \lambda$.

The differences in the values of K given in Column 6 and in Columns 4 and 5 are greatest for the leaning walls and for a vertical wall. From values not given here, it can be seen that as the surface slope increases, the differences diminish; so that, for the earth surface at the angle of repose, for α negative, the coefficients, K, are the same by either of the three methods. Résal, alone, treats the case where α is positive.

The results of neither Boussinesq nor Résal are absolutely exact, their theories leading to differential equations that are not integrable. Boussinesq finds two limits to the thrust, and adds $\frac{9}{22}$ of their difference to the smaller to get the most probable value of the thrust. Résal assumes, as the basis of his analysis, that the stresses along any plane in a mass of earth are parallel, and increase uniformly from the surface downward. This assumption, although true for the Rankine indefinite mass, may not be true for the earth near a retaining wall. Both authors, by independent methods, reach the conclusions above relative to the "limiting plane", Fig. 25, the method of the writer, however, being much the simplest.

It will be observed, from Table 2, that the corresponding values of K do not differ very materially, so that, with a proper factor of safety,

* The numbers in Columns (4) and (5) were made out partly by interpolation from tables, with some computation. For the Boussinesq theory, see tables by Flamant in *Annales des Ponts et Chaussées*, April, 1885. Résal's tables are given in his "Poussée des Terres".

walls designed by either method would not differ in section very materially. For the design of trapezoidal walls, the writer prefers the factor of safety method, exactly as outlined in his paper* previously quoted. In this, the normal component of the thrust is alone multiplied by the factor of safety—the object being to allow, somewhat empirically, for vibration and the lubrication of the back of the wall by water from heavy rains, which may be styled the "time effect". Lubrication might be allowed for by assuming a small value for ϕ' (where the formulas involving ϕ' apply), but vibration, due to heavy trains passing at high speed, defies analysis. Mr. Cain.

The theory of earth pressure against retaining walls is a most difficult one, and eminent mathematicians have exerted their best efforts to effect an exact solution without success, though close approximate solutions have been attained—notably by Résal and Boussinesq. Therefore, any light that can be thrown on the subject is welcome, and the author's comparative sections of triangular walls are very interesting. The subject has taken on increasing interest since a Special Committee of the Society has been appointed to investigate the matter experimentally, and it is hoped that its labors may be fruitful in results.

The great difficulties in reaching correct experimental results, with the many sources of error, are now better realized than ever before, which leads one to hope that results of value may be forthcoming in the near future.

As supplementing the graphical treatment of coherent earth, as given in the writer's paper last cited, a very brief analytical solution will be given of the case of active thrust of earth with a plane upper surface, which makes the angle, i, with the horizontal. The earth, of indefinite extent, will be supposed to be subjected to no external force but its own weight, so that, by a theorem due to Rankine, the pressure on a vertical plane in its interior acts parallel to the surface.

In Fig. 26, ABC represents an infinitesimal wedge of rupture, at a vertical depth, $x = BD$, in feet, below the free surface, the wedge having a length of unity perpendicular to the plane of the paper. The lower face, AC, is supposed to make an angle, α, with the vertical, AD. The angle, α, is always acute and cannot exceed $90° - i$, when AC is parallel to the free surface. The upper face, BC, of the wedge is parallel to the free surface and AB is vertical. For brevity, let the length $AB = b$, $BC = a$, and $AC = l$. As these lengths will be supposed to be indefinitely small, the unit pressures on each face, AB, BC, AC, can be regarded as uniform.

Let w = weight of earth, in pounds per cubic foot;
ϕ = angle of friction;
c = cohesion, in pounds per square foot;

* *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 433.

Mr. Cain.

p = vertical unit pressure on BC;
q = unit pressure on AB, acting parallel to the free surface;
n = normal component of unit pressure, r, on AC.

It is understood that ϕ and c have been determined by experiment,* and it must be carefully noted that, except when $c = 0$, ϕ is not the angle of repose.

The vertical prism of earth vertically over BC has a horizontal section with an area of $a \cos. i$ and a volume $xa \cos. i$, so that vertical pressure on BC is, $pa = wax \cos. i$. The weight of ABC is $\frac{1}{2} wab \cos. i$,

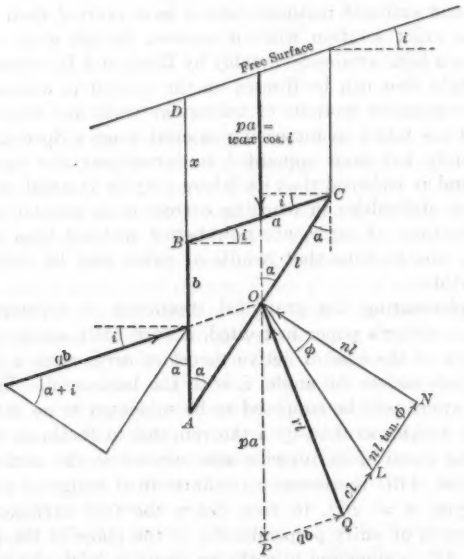

FIG. 26.

which is a second-order infinitesimal (as it involves ab); hence it can be neglected in comparison with the first-order infinitesimal, pa. The pressure on AB, acting parallel to the surface is qb, and the normal reaction on AC is nl. If motion is impending down AC, it is resisted by the full friction, nl tan. ϕ, and the cohesion, cl, both acting up the plane, AC. The resultant of the normal reaction (nl) and the tangential component ($cl + nl$ tan. ϕ) is rl, as shown on Fig. 26, where

* After the methods outlined by the writer in "Cohesion in Earth", or methods based on the same principles. *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1315.

$ON = nl$, $NL = nl$ tan. ϕ, $LQ = cl$, $QO = rl$, and $NOL = \phi$. The three forces, pa, qb, and rl, acting on the wedge, ABC, must be in equilibrium; hence OPQ is a closed triangle, if OP is laid off vertically (to scale) $= pa$, PQ, parallel to the surface, $= qb$, and $QO = rl$. Otherwise, if QO is replaced by its components, QN and NO, equilibrium is indicated by the closed polygon, $OPQNO$. Mr. Cain.

For equilibrium, the sum of the components of pa, qb, and the components $(cl + nl \text{ tan. } \phi)$ and nl, of rl, perpendicular and parallel to AC must be separately equal to zero.

$$p\,a \text{ sin. } \alpha + q\,b \text{ cos. } (\alpha + i) = n\,l \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$p\,a \text{ cos. } \alpha - q\,b \text{ sin. } (\alpha + i) = n\,l \text{ tan. } \phi + c\,l \quad \ldots\ldots\ldots (2)$$

From the triangle, $A\,B\,C$, by the law of sines,

$$\frac{b}{a} = \frac{\text{cos. } (\alpha + i)}{\text{sin. } \alpha}, \quad \frac{l}{a} = \frac{\text{cos. } i}{\text{sin. } \alpha}.$$

On dividing Equations (1) and (2) by a, and substituting the values of $\frac{b}{a}$, $\frac{l}{a}$, and clearing of fractions,

$$p \text{ sin.}^2 \alpha + q \text{ cos.}^2 (\alpha + i) = n \text{ cos. } i,$$

$$p \text{ cos. } \alpha \text{ cos. } \phi \text{ sin. } \alpha - q \text{ sin. } (\alpha + i) \text{ cos. } \phi \text{ cos. } (\alpha + i) = n \text{ sin. } \phi \text{ cos. } i + c \text{ cos. } \phi \text{ cos. } i.$$

Substitute in the last equation the value of n cos. i from the preceding equation, transpose, and factor,

$$p \text{ sin. } \alpha \,[\text{cos. } \phi \text{ cos. } \alpha - \text{sin. } \phi \text{ sin. } \alpha] - q \text{ cos. } (\alpha + i)\,[\text{sin. } (\alpha + i) \text{ cos. } \phi + \text{cos. } (\alpha + i) \text{ sin. } \phi] = c \text{ cos. } \phi \text{ cos. } i;$$

or,

$$p \text{ sin. } \alpha \text{ cos. } (\alpha + \phi) - q \text{ cos. } (\alpha + i) \text{ sin. } (\alpha + i + \phi) = c \text{ cos. } \phi \text{ cos. } i \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The true active thrust corresponds to that value of α that makes $q\,b$ or q a maximum.* For a maximum q, $\frac{d\,q}{d\,\alpha} = 0$; hence differentiating Equation (3) with respect to α, and putting $\frac{d\,q}{d\,\alpha} = 0$ (which cancels one term), we have,

$$p\,[\text{cos. } \alpha \text{ cos. } (\alpha + \phi) - \text{sin. } \alpha \text{ sin. } (\alpha + \phi)] - q\,[\text{cos. } (\alpha + i) \text{ cos. } (\alpha + i + \phi) - \text{sin. } (\alpha + i) \text{ sin. } (\alpha + i + \phi)] = 0;$$

whence,

$$p \text{ cos. } (2\,\alpha + \phi) - q \text{ cos. } (2\,\alpha + 2\,i + \phi) = 0 \quad \ldots\ldots (4)$$

* In Fig. 26, let PQ' represent a less thrust than the maximum, PQ, where Q' (not shown) is on PQ to the left of Q. Draw a line from Q' parallel to QN to the intersection N' with ON and lay off on it $Q'L' = QL = ci$. The new closed polygon of forces, corresponding to $OPQNO$, is $OPQ'L'N'O$. Now, however, $N'OL'$ is greater than ϕ; but ϕ being a constant, it is inconsistent with equilibrium that the angle of friction required by the new construction, $N'OL'$ should exceed ϕ; hence a less thrust than the maximum, $qb = PQ$, is inconsistent with equilibrium.

Mr. Cain. Equations (3) and (4) give the solution, which thus corresponds to the least value of q for which equilibrium is possible. This value of q is the unit conjugate thrust at B, at depth x, corresponding to the limit, as b tends indefinitely toward zero.

When $q = 0$, from Equation (4), cos. $(2\ \alpha + \phi) = 0$; therefore

$$2\ \alpha + \phi = 90°, \text{ or, } \alpha = 45° - \frac{\phi}{2}.$$

On substituting this value of α in Equation (3) and putting $q = 0$, $p = w\ x'$ cos. i, we obtain,

$$w\ x' \text{ cos. } i \text{ sin. } \left(45° - \frac{\phi}{2}\right) \text{cos. } \left(45° + \frac{\phi}{2}\right) = c \text{ sin. } (90° - \phi) \text{ cos. } i$$

$$= 2\ c \text{ sin. } \left(45° - \frac{\phi}{2}\right) \text{cos. } \left(45° - \frac{\phi}{2}\right) \text{cos. } i.$$

Therefore

$$x' = \frac{2\ c}{w} \text{ tan. } \left(45° + \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

where x' = the vertical depth from the surface to where the conjugate thrust, $q = 0$.

In Fig. 26, the case where $q = 0$, would require $P\ Q = 0$, so that $Q\ O$, the reaction of the corresponding plane of rupture, $A\ C$, would be vertical. For $x < x'$, q remains zero and $p\ a = O\ P =$ the weight of the prism of earth vertically over $B\ C$, is entirely sustained by $n\ l$ (corresponding), combined with only a part of $(c\ l + n\ l$ tan. $\phi)$, so that the reaction, $r\ l = Q\ O$, remains vertical for any value of x from zero to x' and there is no thrust, q, on a vertical plane for the depth, x'. In fact, it can be shown generally from Equations (3) and (4) that when $0 < x < x'$, q will come out negative, or Q will lie to the left of P, indicating that a pull, $q\ b$, on $A\ B$ is necessary for equilibrium, if the full friction and cohesion on $A\ C$ is exerted. Therefore, equilibrium is possible when $q = 0$, and only a part of $(c\ l + n\ l$ tan. $\phi)$ is exerted. It follows that, for the unlimited mass of earth, subjected to no force but its own weight, there is no stress on a vertical plane in the mass, for the depth, $x = 0$ to $x = x'$.

When, from any cause, the earth tends to move away to the left of $B\ D$, a pull will be exerted on $B\ D$ for a depth, x', and its value, at depth, $x < x'$, can be found from Equations (3) and (4). This implies that the earth is capable of exerting the tension required. As clayey earths, after heavy rains, often form vertical cracks during the subsequent drying out and contraction, it seems unwise to depend on this tension, either in the case of stable slopes or retaining walls. The tension may be exerted for some time, but eventually it may and doubtless will be destroyed. In the writer's paper,* Fig. 11, page 416,

* "Experiments on Retaining Walls", *Transactions*, Am. Soc. C. E., Vol. LXXII.

refers to the case where tension is supposed to be exerted over the depth, x'; and Fig. 25, page 461, to the case where no tension is supposed to be exerted from the surface to the depth, x', given by Equation (5). Mr. Cain.

The method of solution of Equations (3) and (4) will now be indicated,* using a numerical illustration. Let $i = 30° = \phi$, $c = 100$ lb. per sq. ft., $w = 100$ lb. per cu. ft. From Equation (5), find $x' = \frac{2\,c}{w} \tan. \left(45° + \frac{\phi}{2}\right) = 2 \tan. 60° = 3.46$ ft. At this depth, as proved above, $\alpha = 45° - \frac{\phi}{2} = 30°$. Next, eliminate q between Equations (3) and (4), and substitute $w\,x \cos. i$ for p. The equation can now be solved for x, and on substituting increasing values of α, starting with $\alpha = 30°$, the values of x given in Table 3 can be found.

TABLE 3.—VALUES OF x.

α	x, in feet.	q, in pounds per square foot.
30°	3.46	0
35°	5.26	84
40°	8.42	253
45°	15.00	646
50°	32.70	1 847
55°	124.00	8 738

The values of α give the angles made by the plane of rupture, AC, Fig. 26, for the successive vertical depths, x, from the surface, so that the curved surface of rupture, AS, Fig. 27, can be approximately drawn. It approaches indefinitely parallelism to the surface at great depths for $i = \phi$, assumed. The region, of depth x', sustains no conjugate stress. To find the values of the conjugate stress, q, at the depths, x, given above, substitute in Equation (4) the values of α corresponding and replace p by $wx \cos. i$. The values of q are quickly computed for the corresponding values of α and x given above. The conjugate stress, q, acts parallel to the surface, but it was laid off horizontally in the figure. The curve corresponding is slightly concave upward. When $i = 0$, the surface of rupture is plane; for $i > 0$, it is curved and concave upward, and the curvature increases with i. Thus, α is found to increase with the depth, and may attain the limiting value, $\alpha = 90° - i$, when AC, Fig. 26, is parallel to the surface.

* The method is very long and tedious, and not adapted to practice; hence the writer was led, in his book on "Earth Pressures", to utilize Mohr's "circular diagram of stress", not only to develop the theory of coherent earth, but also to reach numerical results with facility. See Chapter V of that treatise on the complete theory of coherent earth.

Mr. Cain. On substituting $\alpha = 90° - i$ in Equations (3) and (4), we at once find,

$$\left.\begin{aligned} p &= \frac{c \cos. \phi}{\sin. (i - \phi)}; \\ q &= \frac{c \cos. (2i - \phi)}{\sin. (i - \phi)} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Since p is always finite and positive, the case cannot occur when $i < \phi$ or $i = \phi$, but it does occur when $i > \phi$ at a certain depth, which

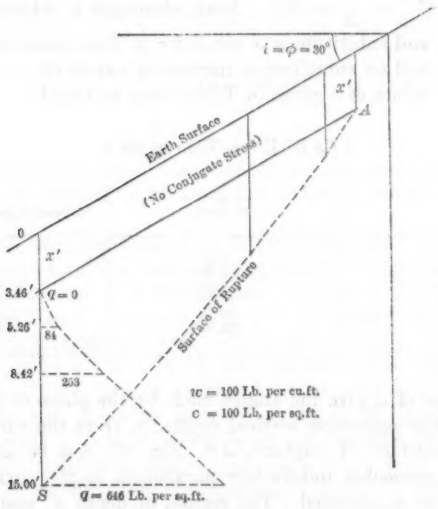

FIG. 27.

call x_0. Thus, substituting $p = wx_0 \cos. i$, in the first of Equations (6), we find the limiting depth at which the surface of rupture is parallel to the surface,

$$x_0 = \frac{c \cos. \phi}{w \cos. i \sin. (i - \phi)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

There is no equilibrium for a greater depth, since α cannot increase farther, no wedge of rupture, ABC, Fig. 26, being formed. Thus slipping is impending at $x = x_0$, and would occur for $x > x_0$, unless the earth is confined by walls, natural or otherwise, the resistance of which thus introduces external forces not contemplated in the theory of the unlimited mass, subjected to no external force but its own weight.

If, in Fig. 26, we drop a perpendicular from B on the "free surface", and call its length h, we have $h = x_0 \cos. i$; whence, substituting in Equation (7), we derive, Mr. Cain.

$$\sin. (i - \phi) = \frac{c \cos. \phi}{w h} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

From this equation, for an assumed value of h, the value of i can be found. This is the maximum inclination of the surface corresponding to the given h. After i has been thus found, $x_0 = \frac{h}{\cos. i}$ can be computed.

When i, increasing, attains the value, $45° + \frac{\phi}{2}$, the value of x_0 reduces to, $x_0 = \frac{2\,c}{w} \tan. \left(45° + \frac{\phi}{2}\right) = x'$, by Equation (5). At this depth, x' (where $q = 0$), it was found above that, $\alpha = 45° - \frac{\phi}{2}$, as should be, since $\alpha = 90° - i$ when AC, Fig. 26, is parallel to the surface. It follows, if there is to be any active thrust, that we must always have $i < 45° + \frac{\phi}{2}$.

The most interesting conclusions relative to the general case, $i > 0$, have now been given. When the earth surface slopes downward to the right from D, Fig. 26, the conjugate thrust still acting parallel to the surface, it can be shown that Equations (3) and (4) hold, on simply replacing i by $(-i)$.

It is not the intention to enter into passive thrust or resistance, but it may be stated that the solution can be effected along lines similar to those used in the case of active thrust.*

For active thrust, the most important case is that for which $i = 0$, or the free surface horizontal. From Equation (4) we obtain, at once, cos. $(2\,\alpha + \phi) = 0$; whence, $\alpha = 45° - \frac{\phi}{2}$, for any x. It follows that the surface of rupture is plane, and that it bisects the angle between the vertical and the line making the angle, ϕ, with the horizontal.

On substituting, $\alpha = 45° - \frac{\phi}{2}$, in Equation (3), putting $w\,x$ for p, solving for q, and reducing,

$$q = \tan. \left(45° - \frac{\phi}{2}\right)\left[w\,x \tan. \left(45° - \frac{\phi}{2}\right) - 2\,c\right] \ldots. (9)$$

* In the writer's "Earth Pressures", the case of passive thrust is fully discussed by aid of Mohr's circular diagram of stress.

Mr. Cain. This equation can be written in the form,

$$q = w \tan.^2\left(45° - \frac{\phi}{2}\right)\left[x - \frac{2\,c}{w} \tan.\left(45° + \frac{\phi}{2}\right)\right].$$

Therefore,

$$q = w \tan.^2\left(45° - \frac{\phi}{2}\right)\left[x - x'\right] \ldots\ldots\ldots\ldots (10)$$

where, Equation (5), $x' = \frac{2\,c}{w} \tan.\left(45° + \frac{\phi}{2}\right)$, is the depth at which $q = 0$, as found above for any i.

The results are as indicated in Fig. 28, where BC is the horizontal free surface, and at depth, x, q (to scale) is represented by FA. The plane of rupture is AD, and $DE = IB = x'$; so that, for the unlimited mass of earth, as shown above, there is no horizontal stress on IB or DE, the weight of EDC being supported by the vertical reaction of DC. The conjugate horizontal stress on the vertical plane, AB, is thus null on the portion, IB, and increases uniformly from I to A, so that its resultant, $\frac{1}{2} w y^2 \tan.^2\left(45° - \frac{\phi}{2}\right)$, acts at $\frac{1}{3}\ A\ I = \frac{1}{3} y$ above A, where $y = x - x'$.

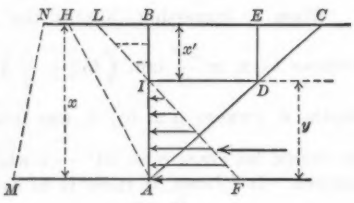

FIG. 28.

The case is different for a limited mass of earth supported by a retaining wall, $AHNM$, which moves over slightly to the left. First, suppose AH to lie below the "limiting plane", making the angle, $45° - \frac{\phi}{2}$, with the vertical. In this case, if the earth is capable of exerting tension in the layer, $IDCB$, the stress on IB will be tensile, increasing uniformly from I to B, the unit tension at the depth, $x < x'$, being given by Equations (9) or (10), corresponding to the minus sign of q. At $x = 0$, the numerical value of this tension is $q_0 = 2\,c \tan.\left(45° - \frac{\phi}{2}\right) = L\,B$, say, and the total tensile stress on $I\,B = \frac{1}{2} x'\, q_0 = \frac{2\,c^2}{w}$. This stress, $\frac{2\,c^2}{w}$, acts horizontally to the right at a point on $A\,B$, $\frac{x'}{3}$ below B.

The total stress on AB is thus the difference between the resultant stresses on AI and IB, and the position of the resultant of the two can

be found by taking moments. This total stress on AB can be put in another form by integrating qdx between the limits $x = AB$ and zero. Using Equation (9), the total stress is found to be, Mr. Cain.

$$\text{tan.}\left(45° - \frac{\phi}{2}\right)\left[\frac{w\,x^2}{2}\,\text{tan.}\left(45° - \frac{\phi}{2}\right) - 2\,c\,x\right].$$

The tensile stress in the upper layer, of depth, x', is transmitted to DE, where its effect is to cause impending motion downward of the wedge, DCE, so that the whole of the friction and cohesion possible, is exerted on AC. In fact, if we regard ABC as the wedge of rupture, it can be independently proved that the total horizontal thrust is exactly that given by the last equation. In this case, the total thrust on the wall can be found by combining the thrust on AB with the weight of earth, AHB.

If, however, AH lies above the limiting plane, the graphical method of Fig. 11* can be applied, in order to find the stress on AH. The position of this resultant stress is uncertain. There are no tensile stresses exerted by the wall on the earth, so that the state of stress on AB is changed, particularly when AH is vertical, in which case, the stress on $AH = AB$ is wholly compressive, though exerted only over a lower portion. The state of stress in the mass, ABC, is complex, involving tension over DE, but only compression over a part of AH. As an approximation, the position of the resultant thrust on AB, for $x > x'$, can be assumed to be the same as in the first case, where AH was supposed to lie below the limiting plane, and the thrust on AH can be taken at the same or a slightly greater height.

The case will not be entered into further, because, for purposes of design of walls, it seems unwise to count on any tension in the layer, BD, as a permanent feature. Then, if AH lies below the limiting plane, the thrust on AI,

$$\frac{1}{2}\,w\,y^2\,\text{tan.}^2\left(45° - \frac{\phi}{2}\right),$$

acting $\frac{y}{3}$ above A, is combined with the weight of earth, BAH, to find the resultant thrust on the wall.

If AH lies at or slightly above the limiting plane, the same method will suffice; but, as AH approaches the vertical, this method will lead to exaggerated dimensions of the wall, and resort can be had to the graphical method of Fig. 25† in order to find the thrust on the wall.

A word may be appropriately added here as to Résal's monumental work, "Poussée des Terres, II, Théorie des Terres Cohérentes" (1910), which is the first complete treatise on coherent earth to appear. The

* "Experiments on Retaining Walls", *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 416.

† *Transactions*, Am. Soc. C. E., Vol. LXXII, pp. 461, 466.

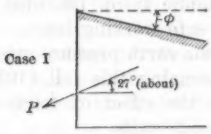
Mr. Cain. solutions of all the cases, for both active and passive thrust, are included in one general formula. In the treatment of the one case of active thrust above, the writer used a different independent variable from Résal, so that the general Equations, (3) and (4), are not the same as the corresponding ones of Résal, but are equivalent, for the case considered, and lead to the same conclusions. Résal's treatment of retaining walls, backed by coherent earth, is cumbersome, and the writer prefers a more exact method, which is in reality shorter and more convincing. This criticism, however, does not apply to Résal's general analysis of earth pressure, which will doubtless always prove as inspiring to subsequent investigators as it has to the writer.

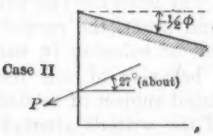
Mr. Braune. G. M. BRAUNE,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer is in sympathy with Mr. Cornish when, in closing his paper, he says:

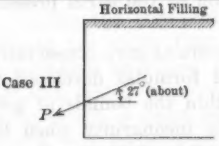
"The writer has never been able to find or think of any good reason for assuming that the slope of surcharge should govern the slope of the resultant earth thrust for great depths."

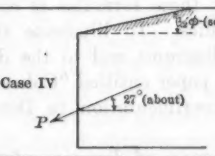
There are two general original theories or principles for determining the earth pressure against retaining walls—namely, Coulomb's and Rankine's.

Coulomb's theory is preferable, for the main reason that the selection of the direction of the earth pressure may be assumed to fit each individual case. If there is no friction between the filling and the wall, the earth pressure would act normally to the back of the wall; if the angle of friction between wall and filling is equal to ϕ', then the earth pressure would be inclined to the normal under an angle that would approach the value of ϕ'. Whether the earth pressure is chosen normal to the back of the wall or inclined does not make very much difference in the magnitude, but it does affect considerably the overturning moment about the toe of the wall; therefore a judicious selection of the direction is an important feature in the design of walls.









Dr. Müller-Breslau has made some experiments at the Charlottenburg Laboratory on earth pressures, and, as the writer believes that the results of these experiments are not generally known, certain parts of them will be given.

In describing these experiments, the height of wall is given as 744 mm.; the filling used was ordinary sand, weighing 1 600 kg. per cu. m. The angle of friction between the back of the wall and the sand was found to be 31° 8′, and the angle of repose 32 degrees. The average results secured on the vertical backs are shown in Table 4. The magnitude, direction, and point of application were determined for different slopes of filling behind the wall. The values, as determined from Coulomb's formula, using the angle of direction as deter-

* Cincinnati, Ohio.

mined from the experiments (27°), are given as a comparison with the experimental values. Mr. Braune.

TABLE 4.

	Magnitude of P. (1)	Direction of P to the normal. (2)	Point of application. (3)	Computed P, after Coulomb, using direction as determined from experiments. (4)
Case I 	91 kg.	About 27°	0.31 h	89 kg. (88.6 kg.)*
Case II 	113 kg.	About 27°	0.33 h	98 kg. (103 kg.)*
Case III 	134 kg.	About 27°	0.36 h	124 kg. (122 kg.)*
Case IV 	195 kg.	About 27°	0.375 h	183 kg. (187.5 kg.)*

* The figures in parentheses in Column (4) give the value of P as computed by the writer for an angle of direction of 27°0′.

In Case 4, evidently a clerical error was made in stating that the angle of surcharge equaled ½ $\phi = 16°$, and giving a computed value of P as 183 kg. for this angle. The value, 187.5 kg., was computed by the writer, using a surcharge angle equal to ¾ $\phi = 24°$.

It will be noticed that the inclination of the filling back of the wall had practically no influence on the direction of the earth pressure, contrary to Rankine's theory. In connection with these experi-

Mr. Braune.

ments, it might be stated that no allowance was made for the frictional resistance between the material and the sides of the box, which would make some changes in the magnitude of the earth pressures, but probably would not have much effect on the direction.

In view of these experiments, Dr. Müller-Breslau recommends that the angle between the direction of earth pressure and the normal should not exceed three-quarters of the angle of repose, even with good drainage and a rough surface on the back of the wall, and provides that the resultant shall cut the base at one-quarter back from the toe.

The nature of the foundation, of course, would control the point of application of the resultant. For unyielding foundations, the resultant could safely fall outside of the middle third, provided, of course, the material is not stressed beyond a safe working limit.

It is the writer's intention to undertake some earth pressure experiments at the University of Cincinnati, commencing this fall (1916), and an endeavor will be made to eliminate the effect of frictional resistance resulting from the pressure on the side-walls.

Mr. Menefee.

F. N. MENEFEE,* Assoc. M. Am. Soc. C. E. (by letter).—The writer has watched, with a great deal of interest and profit, the results of Mr. Cain's plea for more light on the subject of cohesion in earth, bringing out facts bearing directly on the behavior of soil itself, as well as more information on the closely related subject of retaining walls. The following remarks are a result of the writer's attempt to choose a formula for the amount and direction of the earth pressure behind an 80-ft. retaining wall.

It is generally conceded that Rankine's formulas give conservative results, and that in most cases the modified formulas developed by other investigators are rational and well within the bounds of good mechanics. There is, however, one noticeable incongruity when the direction of the resultant thrust obtained by these formulas is compared with that obtained by simple mechanics. To illustrate this point the writer will refer to the author's diagrams and to the discussion by Messrs. Goodrich and Cain on the paper entitled "Cohesion in Earth: The Need for Comprehensive Experimentation to Determine the Coefficients of Cohesion."†

Mr. Cornish mentions the confusing differences of direction of the resultant pressure as given by different formulas, whereas, with a given coefficient of friction between the earth in question and the material in the wall, it appears to the writer that there is only one possible maximum slope to the resultant, regardless of the assumptions made as to the angle of repose or the slope of the surcharge. The writer appreciates the correctness of the formulas considering the assump-

* Jackson, Mich.

† *Transactions*, Am. Soc. C. E., Vol. LXXX, pp. 1315–1341.

Mr. Menefee.

tions, and also the part which conjugate stresses play where there is a surcharge, but believes that if the coefficient of friction of the earth against the wall can be determined, sufficient data immediately become available for finding the slope of the resultant pressure. For instance, referring to Fig. 13, the resultant pressure is given a slope equal to that of the surcharge. The magnitude, by Leygue's formula, is 4 146 lb., which, with the slope given, makes the component, parallel to the back face of the wall, 2 308 lb. In the common friction formula the tangential force necessary to move an object, divided by the normal force, is the coefficient of friction. For the case chosen, then, 2 308 ÷ 4 160 = 0.555, or there must be a coefficient of friction of 0.555 in order to give the force of 2 308 lb. parallel to the back face of the wall. In designing retaining walls, however, do we know that such a coefficient exists, between the earth and the wall, or do we even investigate it? In choosing a formula for finding the resultant pressure, it seems to the writer that we approach the problem backward and reach a conclusion which may or may not be true, for, if the coefficient of friction is not as great as 0.555, no number of formulas, however well deduced, will make it so. Suppose, for instance, that it was determined by experiment that the coefficient of friction for the earth on the wall in question was 0.35; then the maximum possible tangential force on the back of the wall would be 1 455 lb., and the slope of the resultant could not be greater than 1 455 ÷ 4 160, or about 19° 16′. Before any greater force parallel to the back of the wall could be developed, slipping would result.

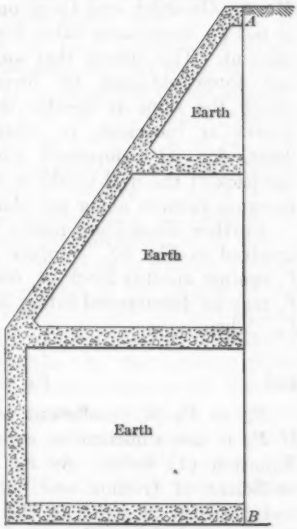


FIG. 29.

In designing some high counterforted walls of the general shape shown in section in Fig. 29, the writer found that the normal pressure of the embankment came on the earth in the cells of the wall. In this case, both friction and cohesion would act, if called on, and cause a downward force parallel to the back of the wall; but that tangential force could never be more than friction and cohesion would develop, and for that reason the writer argues that, instead of attempting to get the slope of the resultant by formula, the coefficient of friction and cohesion of the earth in question should be determined, which, when

Mr. Menefee.

multiplied by the normal force, will give the maximum tangential force that can be developed on the back of the wall.

According to the tabular values in Figs. 1 and 2 in the discussion by Messrs. Goodrich and Cain, one-fourth is not an uncommon value for the coefficient. This means that any resultant force obtained by formulas in which the slope is greater than one-fourth is incorrect, in direction at least, for its component parallel to the back of the wall would be sufficient to cause rupture along the plane, *A B*.

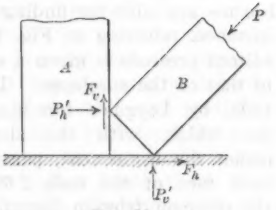

FIG. 30.

Further illustration might be made by resorting to the mechanics involved in Fig. 30. Suppose a block, *B*, is being pushed by a force, *P*, against another block, *A*, resting on the floor, as shown. The force, *P*, may be decomposed into a horizontal force, P_h, and a vertical force, P_v. Then

$$P_v = F_v + P'_v \quad \ldots\ldots (1)$$

and

$$P_h = F_h + P'_h \quad \ldots\ldots (2)$$

$F_v = P_h \times$ (coefficient of friction + cohesion), and no more. If F_v is not sufficient to equalize P_v, then P'_v must increase until Equation (1) holds. As F_v depends on the normal force and the coefficient of friction and cohesion, and F_v is equal in magnitude and opposite in sense to the active vertical component of *P*, then the writer believes that the most direct method of obtaining the vertical component of *P* is by that outlined above.

Mr. Cornish.

L. D. CORNISH,* M. AM. SOC. C. E. (by letter).—Mr. Cain corrects the writer's Sections 15 (Cain) and 23, by stating that, for these cases, where the inner face of the wall lies below his (Cain's) limiting plane, the Rankine method alone applies. Such corrections are justified by his own publications, but the sections as given are correctly computed from the equations derived from the Cain theories, by Mr. Ketchum, who, like the writer, probably was unfamiliar with the Cain theory of the "limiting plane".

Mr. Cain discusses briefly the Rankine sections of Figs. 11 and 12, and states that for years he had pointed out the inaccuracy of the Rankine method when applied to walls with vertical backs, the earth being level at the top. He extends this criticism further (E. P. p. 19) by stating his conclusion drawn from experiments "that the direction of the thrust, as given by Rankine, is never experienced in walls at the limit of stability, except where the surface slopes at the angle of repose."

* Cincinnati, Ohio.

Mr. Cornish.

Though the writer's Figs. 11, 12, and 13, Rankine, and Curves 1, 2, 2*a*, and 2*b*, of Fig. 24, do not in any way verify Mr. Cain's conclusions, they certainly indicate the inconsistency and unreliability of the Rankine theory and formulas when applied to walls with vertical backs. For walls with stepped or battered backs, such as Figs. 15 and 23, with large angles of surcharge, the Cain analysis, as shown by its author, is inapplicable, and the Rankine method must be used.

Mr. Cain also states that the writer is unwarranted in his assumption that the variation of p, in Figs. 2 to 8, offers any criterion for judging of what the variation should be for Figs. 9 to 15, and, to substantiate his statement, offers certain arguments based apparently in part on the assumption that conclusions relative to walls 10 ft. high should not be based on the experimental data of Leygue for retaining boards 8 in. high. If such was his intention, it is due to a misunderstanding of the writer's criticism, as it is plainly evident that the variation in p is entirely independent of the height of the walls. The writer criticized the Cain formulas in only two particulars: one was with reference to Figs. 14 and 15 (Cain), being but slightly larger than Figs 7 and 8, which is explained by the limiting plane theory, which necessitates the use of the Rankine theory for Fig. 15. The other criticism was that the Cain formula produced a section (Fig. 11, Cain) larger than Fig. 10 (Cain), whereas a smaller section might reasonably be expected because the experimental section, Fig. 4, is smaller than the section shown by Fig. 3. It is not apparent how cohesion can account for such a variation.

The experiments of Dr. Müller-Breslau, cited by Mr. Braune, are extremely interesting, and indicate quite conclusively that the slope of the surface has little or no influence on the slope of the resultant earth pressure. It is to be hoped that Mr. Braune's proposed experiments will develop some valuable data on the vexatious question of the direction of the resultant pressure.

The writer trusts that the paper and discussions have been of some material benefit in emphasizing the necessity for systematic experimentation until sufficient data are obtained to permit the development of working formulas on which all members of the Engineering Profession can agree; and he herewith tenders his thanks to the gentlemen who have so kindly co-operated with him by engaging in the discussion.

Paper No. 1385

A COMPLETE METHOD FOR THE CLASSIFICATION OF IRRIGABLE LANDS*

By F. H. Peters, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. T. Kennard Thomson and G. N. Houston.

Synopsis.

This paper deals with the classification by the Dominion Government of a very large area of irrigable land developed by the Canadian Pacific Railway Company in the Province of Alberta. The reason for undertaking the work is stated. The climatic, soil, and crop conditions of the area under discussion are described, and, as governed by these, the basis of the classification is stated. Then the actual manner in which the classification of the land was made is described in detail.

The Reason for Government Classification.—The development of the Western Section irrigation block was carried out by the Canadian Pacific Railway Company. Construction was started in 1903, and the project was practically completed in 1910. The development covers a gross area of about 1 037 000 acres, of which more than 223 000 acres are irrigable. There are 17 miles of main canal, 254 miles of secondary canals, and 1 300 miles of distributaries. The total cost of construction has been $4 325 000, and it is estimated that a further expenditure

* Presented at the meeting of November 1st, 1916.

of $1 500 000 will be necessary to replace wooden structures with concrete. About 66% of the irrigable lands have been sold.

The law in force in Alberta, and under the provisions of which the project was constructed, is the Dominion statute entitled the Irrigation Act.

This Act contains a clause to the effect that, before a water license is granted to any person or corporation, a certificate must be issued, by the Chief Engineer appointed under the Act, certifying "that the works as constructed are capable of carrying and utilizing a stated quantity of water". It is necessary to certify to the carrying capacity of the works because this has a fixed ratio to the irrigable area, based on the legal duty of water, which is fixed. The Minister of the Interior, who is created by the Act the high executive officer of the Crown, decided that in the case in question the fullest intent of the quotation above should be carried out, and ruled that "utilization" should be held to mean "beneficial utilization".

This decision made it necessary to make a complete classification of all the irrigable land, and this had to be based on a rigid definition of the words "beneficial use" in terms of dollars and cents.

Determination of the Basis for Classification.—It was admittedly a difficult problem to assign a cash value to the term "beneficial use", which made necessary a balancing of the added returns of irrigation against the added cost of irrigation—both in comparison with dry farming.

The so-called "dry farming" method of agriculture was generally practiced in the Province, and the value of the returns from this method of agriculture were known. The value of returns from irrigation agriculture in the district was not known, because there had been very little actual irrigation. It was necessary to make a conservative estimate of the added returns over dry farming due to irrigation.

The added cost of irrigation was considered to be made up of four items: the additional first cost of the irrigable land over non-irrigable land; the annual charge for water; the ordinary cost of smoothing and leveling the land to allow of an even spreading of the water; and the concentrated cost of reaching, from the head-gate, certain areas of land which, being cut off by a depression, required embankment or flume construction, or, being in a depression, required drainage. The

first two items were known, and the average cost of smoothing and leveling was estimated.

The governing element in the basis of the classification, which will be described in detail later, was the item of concentrated cost.

In making an estimate of the added returns of irrigation, it was necessary, because of the lack of actual data for the district, to make a very broad study of all the essential features, and these are dealt with under the headings of "Climate", "Topography and Soil", and "Crops".

Climate.—The tract lies approximately 120 miles north of the International Boundary and 50 miles east of the foot-hills of the Rocky Mountains, and has a general slope from west to east. The elevation of the western boundary is about 3 300 ft. above sea level and that of the eastern end is about 2 900 ft.

The climatic conditions are very similar to those in Northern Montana and the higher valleys of Colorado, where irrigation has been practiced successfully for years. The average growing season between spring and fall killing frosts (32° Fahr.) is about 101 days.

Tables 1 and 2 show the temperature and precipitation for Calgary and Gleichen, which are nearly at the west and east ends of the tract, respectively. The irrigation season extends from May 1st to September 30th.

Topography and Soil.—The topography is generally rolling, with rather steep slopes which locally run up to 10 or 15 ft. in 100 ft. There are many cross-drainage lines, and, in order to avoid expensive crossings, the locators were forced to drop the elevation of the canals, thus losing command of some of the higher and better lands. The topography is somewhat smoother in the eastern than in the western portion of the tract.

The soil conditions over such a large area, of course, have a wide variation. Extreme conditions, varying from almost pure sand to very heavy clay, may be found, but, speaking generally, the soil is the usual clay loam commonly found on the prairies of the Northwest. As a whole, the area is overlaid with a surface soil containing a good proportion of humus, which proves very fertile. In general, the subsoil is a heavy clay, making it imperative to apply the irrigation water with care, in order to avoid water-logging the land. Local conditions where the soil is heavily impregnated with white alkali are found, but black alkali is rare. As will be indicated later, great care was taken

in the classification to exclude as non-irrigable any areas in which the soil analysis showed this great enemy to irrigation to exist in dangerous quantity.

Crops.—The leading crops in the Province are hard wheat, oats, and barley. The hardier strains of alfalfa grow excellently under irrigation, and small fields throughout the tract produce from 3 to 4 tons per acre in two or three cuttings. Experimental plot work has indicated that a heavy yield of sugar beets, with a high saccharine content, can be raised under irrigation. The irrigation tract under consideration is so young in development as yet that no good general crop reports can be obtained. In the Lethbridge District, about 100 miles to the south, however, there are about 15 000 acres under the alfalfa crop which produce about 4 tons per acre under irrigation.

For purposes of comparison, the following points are noted with reference to this tract. The general elevation is about 2 850 ft.; the soil conditions are more favorable as regards texture and absence of alkali; the annual precipitation is about 2 in. less; and the annual mean temperature is about 4½° Fahr. higher.

The Dominion Government Experimental Farm at Lethbridge has kept records of the returns from irrigated and non-irrigated crops since 1908, and Table 3 has been compiled by using these actual returns and inserting the prices which were obtained each year, f. o. b. cars, at Lethbridge. This table must be accepted as showing results from plots on the experimental farm, which are no doubt higher than those obtained by the average farmer, but it is considered that the table shows truly the relative increase due to irrigation. To be indicative of the crops commonly raised under irrigation in the district, the table should include alfalfa and timothy hay.

Basis of Classification Adopted.—The basis of classification adopted was as follows: Land shall be classified as irrigable:

(1).—If it lies at a lower elevation than the point of delivery, after allowing a reasonable grade for a farm lateral.

The point of delivery shall be deemed to be a point 3 in. below the crest of the measuring weir at or within the farm boundary. Where this measuring weir is not at or within the farm boundary, the point of delivery shall be the elevation of full supply level in the lateral supplying the field outlet, and all measuring weirs shall be built in

accordance with the plan of farm weirs filed with the Commissioner of Irrigation and dated November 1st, 1908.

The grade of farm laterals, when a factor in land classification, will be considered reasonable:

(*a*) Where the natural slope of the ground is less than 0.10 ft. in 100 ft. at a rate not less than 0.05 ft. in 100 ft.;

(*b*) Where the natural slope of the ground is greater than 0.10 ft. in 100 ft. at a rate of not less than 0.10 ft. in 100 ft.;

(*c*) Where the slope of the ground is at or near the critical slope of 0.10 ft. in 100 ft. at either of the grades mentioned in clauses (*a*) and (*b*), such as good and reasonable practice demands.

Extremely flat country may be irrigated by checks and flooding, and the grade of the farm lateral need not be considered in such cases, it being understood that the Minister of the Interior, or officers appointed by him, shall be the final judges of what constitutes "extremely flat country".

(2).—If such land can be reached by an estimated concentrated expenditure at one or more points, for embankments, flumes, etc., not in excess of $8 per acre for the land to be served and benefited through them.

(3).—If such land can be served by a second or other delivery at a cost not in excess of $8 per acre for the land to be served and benefited through them.

(4).—When lying in a depression, if it can be drained at a cost not exceeding $8 per acre, and is suitable, arable land which would be benefited by irrigation.

(5).—The prices to be made use of in estimating the cost of embankments, flumes, or other structures, shall be, unless otherwise ordered by the Minister of the Interior:

Earth fill or excavation.....12 cents per cu. yd.
Lumber in place on any structure.....$40 per 1 000 ft. b. m.
Rock rip-rap.....50 cents per superficial yard.

(6).—In all unusual or exceptional cases, which are not covered by the preceding paragraphs, the classification will be made by officers of the Department, under the direction of the Minister of the Interior, in

a fair and reasonable manner, and will be based on the beneficial use of water.

Much attention was given to the question of the maximum slope permissible for land to be classified as irrigable, but this was not included in the official basis. The engineer in charge, in approving the classification, was guided by the rule that generally a maximum slope of 10 ft. in 100 ft. was permissible, and where very small areas only were concerned a maximum slope of 12 ft. in 100 ft.

As indicated under the heading, "Determination of the Basis for Classification", the classification was based on a cost of $8 per acre,

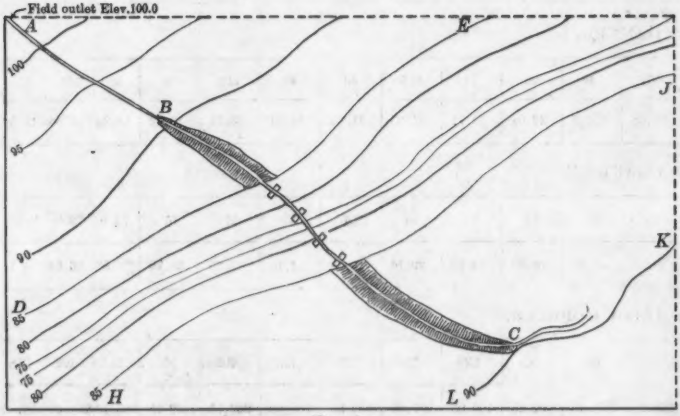
but as this is a very crucial point, many details are given in order to explain just what the figure means.

Under the conditions of its land sale contract and water agreement, the Company delivers the water to at least one point on each parcel of land, usually of 160 acres, and the cost figure was applicable only to the added expenditure necessary for the farmer to distribute the water over the land. The figure was not a general one applied to the total irrigable area in each parcel, and including the ordinary costs of leveling and smoothing the land, but was the concentrated cost of reaching certain areas of land which, being cut off by a depression,

required embankment or flume construction, or, being in a depression, required drainage.

The following study, which was made by the writer in examining the cost data before the basis of classification was adopted, will make the point quite clear.

Referring to Fig. 1, the area, *A-D-E*, can be easily irrigated without any high expenditures for flumes, embankments, etc., and the $8 figure does not recognize any expenditure necessary for this area. The area, *H-J-K-L*, is separated from the field outlet by a wide depression, and it required a costly raised ditch and flume to carry water from *B* to *C*. The basis of classification means that if the cost of the raised ditch and flume from *B* to *C* is less than a concentrated ex-



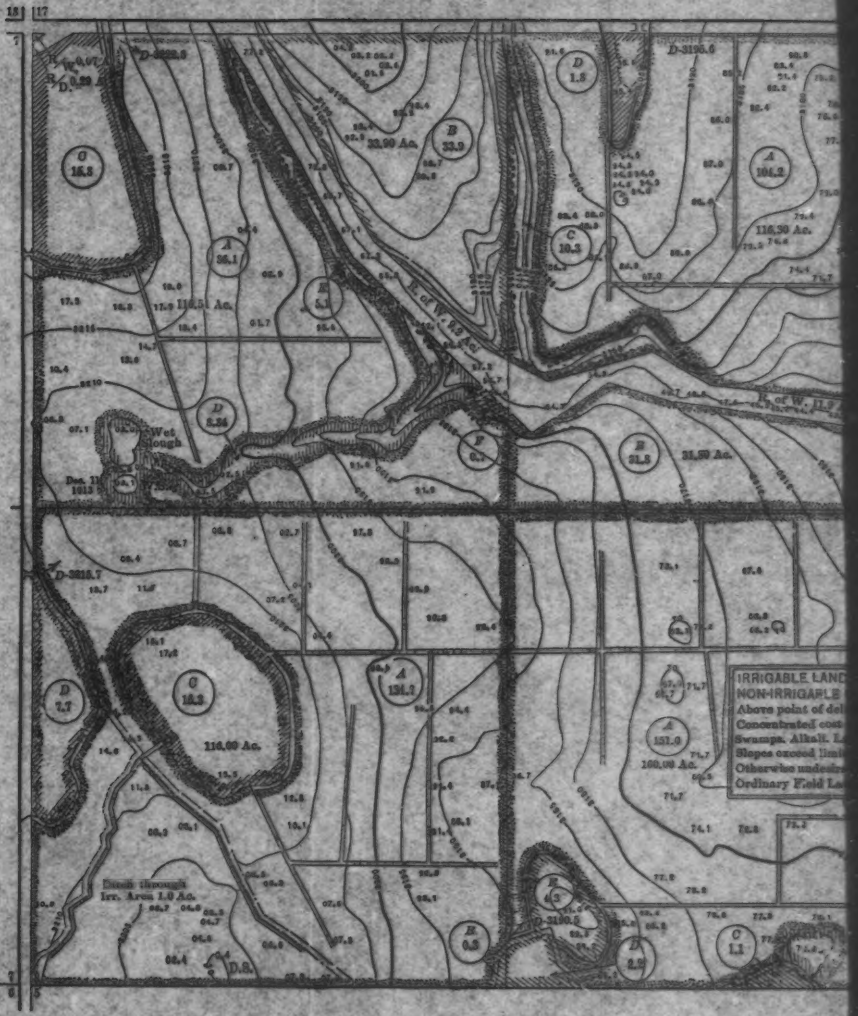


FIG. 1.

penditure of $8 per acre on the area, *H-J-K-L*, then *H-J-K-L* shall be classed as irrigable. Again, the $8 figure does not recognize the ordinary costs of preparation necessary for the irrigation of *H-J-K-L* after the water has been conducted to *C*. Now, in truth, it would require a certain expenditure per acre in smoothing the land, building field laterals, distributaries, etc., to irrigate *A-D-E*, and similarly a certain expenditure per acre would be required to irrigate *H-J-K-L* after water had been conducted to *C*.

In considering how much may be profitably spent in preparing land for irrigation, it is usual to compute it at so much per acre for the whole parcel of land, this figure including all flumes, embankments,

ditches, etc., and also the smoothing of the land to allow of proper irrigation.

The writer will now endeavor to show what the concentrated cost of $8 per acre means for different cases, and for the average case, couched in the usual terms, as explained in the foregoing paragraph.

If it is assumed that the average piece of land will require an expenditure of $4 per acre for smoothing, ditches, etc. (there being no clearing of any kind necessary in this district), and if this is combined with the concentrated cost of $8 per acre, it is seen immediately that the actual total cost of preparing any land which requires the "concentrated" expenditure is really $8 plus $4, or $12 per acre. It must be realized that in every parcel of land, considered as a unit, there will be a varying proportion which can be prepared for irrigation with an expenditure of only $4 per acre, and of other land which will require in addition to this the "concentrated cost" expenditure of $8 per acre.

TABLE 4.—Cost per Acre for Structures and Preparation of Land for Irrigation.

No. of acres of good land.	Cost per acre.	Total cost.	Percentage of land requiring concentrated expenditure.	Number of acres.	Cost per acre.	Total cost.	Grand total, in acres.	Grand total cost.	Average cost per acre.

60	4	240	40	40	12	480	100	720	7.20
50	4	200	50	50	12	600	100	800	8.00
							600	$3 600	$36.00
					Averages.....		100	$600	$6.00

Note.—Average cost per acre for structure and preparation of land for irrigation, say, $6.

It is not claimed that Table 4 is absolutely accurate in any way, but it shows that, for the average piece of land, the cost distributed over the whole irrigable area will be about $6 per acre, and that for the piece where 50% requires the concentrated expenditure (which

must be considered a high percentage) the cost per acre in a similar way will only be about $8.

Since the classification has been completed, this study has been checked by actual results, and it has been found that the average total cost per irrigable acre, including the $4 charge for smoothing and leveling, has been $5.70.

Surveys and Plans Required.—It was realized that the basis of the very complete classification anticipated must be very accurate contour plans showing the detailed topography of all the area to be classified. The Canadian Pacific Railway Company was required to furnish the necessary plans, and as it had made topographical surveys covering only a small portion of the total area, it was necessary to make new surveys of the remainder.

The specifications for these plans were as follows:

1.—The scale of the plans shall be 400 ft. to 1 in.

2.—On every plan shall be shown 5-ft. contours in heavy lines, and wherever the slope is less than 2 ft. in 100 ft., 1-ft. contour lines shall be shown in thin lines.

3.—All "ring" contours in hollows or on summits shall be located on the ground by at least four points.

4.—All sloughs or other areas covered by water shall be located by at least four points.

5.—The tracings submitted in duplicate to the Commissioner of Irrigation shall be made from the original plane-table plans made in the field.

6.—The location and elevation of every field outlet shall be shown plainly on each plan. The elevation of the field outlet shall be a point 3 in. below the crest of the measuring weir, if located at or within the farm boundary; where this measuring weir is not at or within the farm boundary, the elevation of the field outlet shall be the elevation of full supply level in the lateral supplying such outlet.

7.—The area and location of such land as is commanded by the ditches, but which is plainly rendered non-irrigable owing to alkali or any other cause, shall be shown on the plans.

8.—No contour lines need be shown above the falling contour which passes through the elevation of the field outlet and falls from it at the following rates:

(*a*) Where the natural slope of the ground is less than 0.10 ft. in 100 ft., at a rate not less than 0.05 ft. in 100 ft.;

(*b*) Where the natural slope of the ground is greater than 0.10 ft. in 100 ft. at a rate not less than 0.10 ft. in 100 ft.;

(*c*) Where the natural slope of the ground is at or near the critical slope of 0.10 ft. in 100 ft. at either of the rates mentioned in (*a*) and (*b*), such as good and reasonable practice demands.

9.—Every precaution shall be taken to make the plans as accurate as possible within the limit of a reasonable expenditure of money. The maximum error in the plans area delineated by the critical contours shall not exceed 2½% in any quarter-section of land.

10.—The exact location of any of the Company's distributaries or secondary canals which run through any parcel of land, shall be the outside lines which determine the land that is made non-tillable by the ditch construction or other works.

11.—All distinct drainage lines or channels shall be traced on the ground and shown on the plans.

12.—All plans submitted should be to a standard, over-all size, for the purpose of filing, and should not exceed 18 by 18 in. This will permit one section to be shown on each plan at a scale of 400 ft. to 1 in., and one quarter-section at a scale of 200 ft. to 1 in.

13.—It is understood that, under Secondary Canal *C*, about 90 000 acres of land have already been contoured to a scale of 1 000 ft. to 1 in. For this particular land, Paragraph 5 of these specifications shall be inoperative.

14.—It is understood that, under Secondary Canals *A*, *B*, and *C*, about 100 000 acres of land have already been surveyed to a scale of 200 ft. to 1 in. These surveys do not show contours, but show a classification of land, based particularly on soil conditions. These plans with descriptive notes will be accepted by the Commissioner of

Irrigation, who will reserve the right to call for such additional information on any particular plan as he may require for the purpose of the re-classification.

With reference to Clause 13 of the Specifications, this meant in practice that the plans submitted were to the general scale of 400 ft. to 1 in., but were enlarged from the original field plans (at 1 000 ft. to 1 in.) which had previously been prepared by the Company.

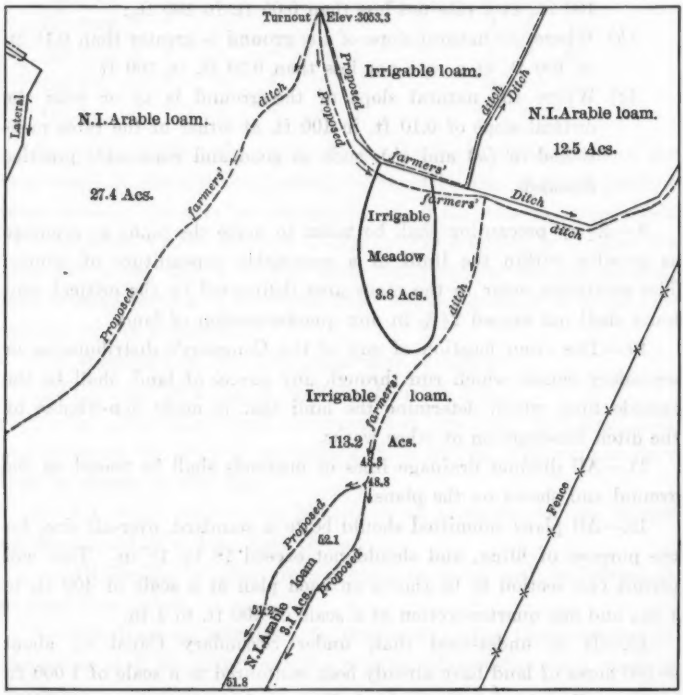

FIG. 2.

The left half of Plate III shows a typical plan as submitted by the Company, and Fig. 2 shows a typical plan as submitted under the special Clause 14 of the Specifications.

The Company has constructed all the canals and ditches which deliver the water to the field outlet for each parcel of land. The usual

parcel to which a delivery is made is 160 acres, this being a legal quarter-section, the parcel usually dealt with in selling. In making the classification it was necessary to know the exact parcel of land that was to be served from any field outlet.

In the case of land already sold by the Company, agreements filed with the Department showed the parcels owned and included under each water agreement, and in these cases such areas were considered as one. In other special cases, usually concerning fractional areas, the Company's plans submitted showed by a conventional sign the special parcels that were to be sold together, and were so dealt with as regards parceling in the classification.

The cost of preparing the plans, under the general clauses of the Specifications, was 23 cents per acre, this being based on the total area, irrigable and non-irrigable, covered by the contour plans.

Procedure of Classification.—The procedure of carrying out the classification was as follows:

1.—Submission of contour plans by the Company;
2.—Preliminary office classification of plans;
3.—Field classification of plans, including soil analysis;
4.—Final office classification of plans;
5.—Final approval of plans by the engineer in charge.

Preliminary Office Classification.—The Canadian Pacific Railway Company operates at Calgary a lithographic print process, and, in addition to the original tracings, supplies an extra plan on paper.

The paper copy of the plan was then classified in the office by projecting the necessary farmers' ditches from each farm delivery shown and delineating irrigable and non-irrigable areas in accordance with the basis of classification decided upon.

The purpose of the office classification was to delineate the irrigable and non-irrigable areas which were dependent on topography, that is, cost of field irrigating ditches, cost of drainage ditches, excessive slopes, etc. In addition, there were excluded all areas reserved by the Company as right of way for main canals, and the areas rendered non-tillable by the smaller company laterals which ran through any farm and for which easement had been reserved in the land contract sale to the farmer.

The results of this office classification were scheduled on a "Land Classification Detail Sheet", Fig. 3, this sample referring to the right half of Plate III.

The cost data for ditches, embankments, flumes, etc., used in the office classification were taken from the standard design sheets which are shown as Figs. 4, 5, 6, and 7, which were worked up for office use from the basis of classification determined upon.

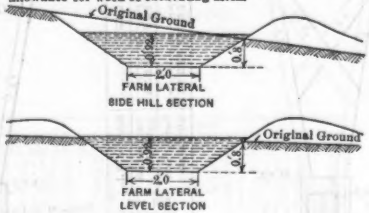
Field Classification.—The paper copies of the plans, together with the land classification detail sheet, were then sent out to the field, where, map in hand, the classification was carefully examined on the ground by the engineer in charge of the work. This engineer was supplied with a motor car for quickness of transport, and was assisted by three engineers, each accompanied by an instrumentman, a rodman, and a teamster with a democrat. The field work was most carefully examined, and, whenever any undesirable areas were found,



Use double fill when water level is from 0.3 to 1.7 above ground level.
Use fill as below when water level is more than 1.7 above ground, if less expensive than flume.

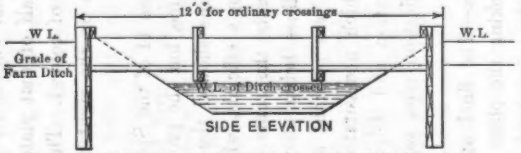
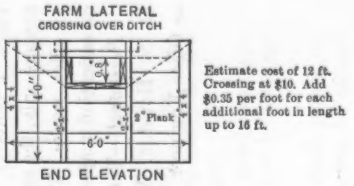
such as alkali conditions, land not fit for cultivation, or any other conditions not shown by the contour plans, these areas were delineated by the level-compass-stadia method, and, where greater detail was necessary, by the plane-table. In many cases, also, of critical cost, an actual profile was run in the field for irrigation or drainage ditches, embankments, or flumes.

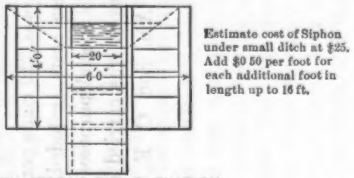
One of the most difficult features was the determination of unsuitable soil conditions, and the greatest care was exercised in excluding alkalied lands or lands likely to be alkalied by irrigation where the cost limit would not allow of efficient drainage. In connection with this work many soil samples were taken with the soil auger or post-hole digger, in order to determine the physical structure of the surface soil and the subsoil, or the presence of alkali in dangerous quantity. The quantity of alkali was determined by submitting soil samples to complete chemical analysis.



It was fully realized that the field classification was the most critical operation in the general procedure, and that, following the careful topographical surveys and the office classification, the net irrigable areas capable of beneficial irrigation could only be determined by a careful inspection in the field by an experienced man who had a full knowledge of practical agriculture under irrigation.

Final Office Classification.—The paper plans and classification sheets which had been used in the field were returned to the office with copious pencil notes and, where field traverses had been made or profiles run, these were plotted on separate sheets in the field and attached to the plans. One of the tracing linen plans was then worked up in the office, and included all the corrections to the office classification made in the field. The scheme adopted was to outline on the tracing the irrigable areas, the non-irrigable areas, and the right of way reserved by the Company. By the use of different colors, in accordance with an adopted schedule, the reason that each area was rendered non-irrigable was shown. Each plan showed a whole section of land, and at the bottom there was filled in a schedule showing for each quarter-section the total irrigable land, the total non-irrigable land, and the right of way reserved by the Company. The land classification detail sheets, showing the summation of the irrigable and non-irrigable areas, were also corrected. Each separate detail was referenced to the finished





Siphon under ditch to be used where grade of farm ditch is too low to clear W.L. of ditch to be crossed. Where dimensions are not shown vary lengths to suit conditions. Allowance in estimate of cost is made to cover cost of tar between all joints of wood.

Crossing over ditch to be used where grade of farm lateral is higher than W.L. of ditch to be crossed. Give box as much fall as circumstances permit. If necessary to drop grade after crossing, make box long enough on the lower side to clear the bank of the ditch crossed.

Estimate cost of 12 ft. Crossing at $10. Add $0.35 per foot for each additional foot in length up to 16 ft.

Estimate cost of Siphon under small ditch at $25. Add $0 50 per foot for each additional foot in length up to 16 ft.

DITCH CROSSINGS

STANDARD DESIGNS FOR FARMERS LATERALS & STRUCTURES

USED IN ESTIMATING COST

FIG. 7.

plan by the use of the letters, *A, B, C,* etc., which same letters were used to denote the segregated areas on the plan.

The right half of Plate III shows the final classification plan worked up from the plans shown on the left half of that plate (different conventional edgings being used instead of colors). The land classification sheet referring to the plan shown on the right half of Plate III is also shown.

With the special plans submitted under Clause 14 of the Specifications, the result obtained was practically the same, but the procedure was necessarily somewhat different. These plans showed the result of a classification in the field by the Company's officials, who had worked under instructions which were practically the same as the basis of classification adopted. No contour lines being shown on these plans, no preliminary office classification was possible, and all the checking had to be done in the field, which necessitated considerable additional work in determining elevation and delineating areas by the field assistants. The final classification plan was prepared in the same manner as described above.

Final Approval of Plans and Classification.—The final approval was made by the engineer in charge after checking the plans to see that the field notes submitted had been properly interpreted in the office in making up the final copy. The cost of making the classification based on the total area inspected was 16.2 cents per acre, of which 7 cents is chargeable to office work. Based on the irrigable acreage only, the cost was 32.9 cents per acre with 14.1 cents chargeable to office work. These costs included making duplicates of all the classification maps for special purposes of record.

Personnel.—The work was carried out under the direct charge of G. N. Houston, M. Am. Soc. C. E., and Mr. R. C. Spitzer acted as Office Engineer.

DISCUSSION

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E. (by letter).—This clean-cut paper is of especial interest to the writer because he was on the survey for the first railroad, the Canadian Pacific, to be built in that section of the country, 33 years ago.

At that time nobody ever expected to see this road pay for itself, as it was built as a political necessity to keep British Columbia and the great Prairie Provinces in the Dominion.

An old farmer described the conditions then as follows: "Forty degrees below zero, 50 miles from water, 500 miles from fuel, God bless our home."

The paper would be even more interesting, if made a little more general by stating, for instance, the quantity of water required for irrigation, and whether the supply is continuous or intermittent during the summer. As the water comes from the mountains, the writer assumes that the supply would be cut off by the ice in winter. For instance, even the North Saskatchewan, at Saskatoon, a mighty river in summer, is practically dry in winter.

It would also be interesting to know what the good and poor lands sell for, before and after irrigation.

The alkali lands referred to remind the writer that he heard only last week why his hair had turned white when quite young. It was discovered, not very long ago, that all young men in the Canadian Northwest have become white-haired because of the alkali in the water and also because of the quantity of ammonia used for purifying the water.

The author states that the climatic conditions are the same as in Northern Montana, but as the range of temperature is more interesting than the mean, why not state what they are?

Is it not true that the depth of the rich top soil is 15 ft. or more in vast areas of the Canadian Northwest? It may be more modest not to extol the richness of the soil, etc., but, at the same time, one would like to know the facts. The price for excavation and fill, 12 cents (as stated by the author), seems to be remarkably low, especially as the quantities of material moved in any one spot are so small.

The sections of the cuts and excavations are so small, and the wooden superstructures are so light, that one wonders if they do not require very considerable repair every spring.

The Canadian engineers, instead of using blue or black prints on paper, make black prints directly on cloth, and these can be placed in a pocket or bag as readily as a handkerchief; and the writer is

* New York City.

Mr. Thomson.

surprised that such a great improvement has not already been generally adopted by American engineers.

Table 3, showing the increased value of land each year due to irrigation—an increase from 0 for wheat to $200 an acre for potatoes—is exceedingly interesting. In New York State, frost in a single night will sometimes destroy all the crops; and then a month or more of good weather will follow with no frosts. Is this the case in Alberta?

Some day it will be possible to generate by electricity sufficient heat for a night or two to afford sufficient protection from such frosts; and it will be possible even to go further and, by artificial heat and light, produce two crops where only one grows now.

Mr. Houston.

G. N. HOUSTON,* M. AM. SOC. C. E. (by letter).—Irrigation development comes under one of two classes: that affecting areas where irrigation is a necessity, and that affecting areas where it is only desirable. Irrigation is a necessity where, other conditions being favorable, the precipitation is insufficient to produce a profitable crop. It is desirable where the precipitation, other conditions being favorable, is insufficient to produce the maximum profitable yield of the particular crops adapted to the region.

The possibilities under the first class have been about exhausted, except as the area is extended by conserving the water and rendering it more efficient in crop production. Under the second class, there is a great deal yet to be accomplished.

It has not been considered necessary to make any extensive study of the climatic conditions in connection with irrigation development in the United States, because the projects have been nearly all confined to the arid and semi-arid districts, where the desirability of irrigation had been demonstrated in a small way by the individual farmer, or by the small community of settlers. It was assumed that like benefits would accrue, in this district, wherever water could be applied to arable land, and the engineer has been concerned principally with transporting and applying this water.

In connection with projects of the second class, however, that is, where irrigation is not a necessity but is simply desirable for increasing the yield of an already profitable crop, the development is reaching out into the more or less humid regions, and the question of desirability is becoming more and more complicated. In these cases a study of the climatic conditions is necessary, especially with regard to the precipitation, in order to determine whether the probable additional profits due to irrigation would be sufficient to justify the cost of the system.

Monthly averages of the precipitation as published do not furnish the necessary data for this study. The daily distribution of the rainfall,

* Denver, Colo.

Mr. Houston.

or, in other words, the occurrence of drought periods during the cropping season, must be considered, as this is the chief factor affecting the yield of the crop. In connection with the work of which the paper treats, the writer had occasion to make such a study of the climatic conditions of several points in Southern Alberta and Northern Montana, a summary of which is given in Table 5. A graph was made showing the daily rainfall during 11 years for each of the locations, and the drought periods were picked out. Column 1 shows the length of each period; Column 2 shows the total precipitation which occurred during each drought; Column 3 shows the number of days during the drought on which rain fell; and Column 4 shows the maximum rainfall on any one day during the drought.

The effect which a period of light rainfall may have on a crop depends on a number of factors, such as the rate of evaporation, as affected by humidity and wind velocity, the kind of crop and the stage of its growth, the general texture of the soil, and whether or not it has had any preparation to receive and conserve the moisture. These matters must be given due weight in determining the desirability of irrigation, especially on those tracts where the climatic conditions are nearly humid.

In the development of irrigation projects, too little attention has been paid to the character of the soil of the land proposed to be put under water. This, however, is simply one phase of the general tendency of the promoter, the investor, and in many cases the engineer, to disregard the conditions under which the investment is to be returned. Large expenditures have been made in order to deliver water to land the character of which, except as regards surface appearance, has been practically unknown.

Some of this land is impregnated so heavily with alkaline salts that it cannot produce sufficient under irrigation to return interest on the investment. Where the alkali shows on the surface in large white patches, there is little danger of the land being included in an irrigation scheme without provision being made for its reclamation. The subsoil, however, may be very heavily impregnated and there may be very slight indications, or none at all, on the surface, until after the project is in operation, when the salts are brought to the surface by the direct application of water or seepage from a near-by ditch. The result is that the investor suddenly realizes that he will be obliged to build an expensive drainage system, to wash out the alkali, or cut out this land entirely from the project. In the latter case, in order that the investment shall be returned, the remaining land must be burdened with an additional tax, in proportion to the part excluded, which possibly it is not able to stand.

No irrigation project should be built until a careful study of the soil conditions has been made, not only in regard to the topography

Mr. Houston.

Mr. Houston.

and alkaline content, but also a classification as to its general texture and fertility. With data of this kind as a basis, the prices of the various classes of land can be fixed, and a variable system of payments arranged so that there will be a reasonable possibility of the settler meeting his obligation from the produce of the land.

In the case under discussion, a typical sample of the field notes of the soil investigations is shown in Fig. 8.

A post-hole digger was found to be most satisfactory for obtaining the samples, although several kinds of soil augers were tried. The depth of the hole was usually 6 ft. Samples were taken whenever the soil changed in color or texture. These were packed in 1-qt. glass preserve jars, in order to retain their moisture content, and shipped to the Dominion Chemist for analysis.

The maps were carried in the field in a galvanized-iron case, hinged at the right side and having a beaver-board back. The following abbreviations were used in the soil investigation field notes.

W &.	Very wet.	Water in the hole.
W.	Wet.	Water will drip from sample.
D &.	Very damp.	Water can be squeezed from sample.
D.	Damp.	Slightly soggy.
D—.	Less damp.	Putty-like.
M.	Average soil mixture.	
P.	Dry and powdery.

Paper No. 1386

THE YALE BOWL*

By Charles A. Ferry, M. Am. Soc. C. E.

With Discussion by Messrs. Thomas C. Atwood, J. B. French, H. C. Keith, H. F. Dunham, Henry C. Hitt, Alexander S. Lynch, and Charles A. Ferry.

Synopsis.

This paper is descriptive of the new amphitheater constructed for the Athletic Department of Yale University. It is the largest structure of the kind in the world, and provides seating accommodation for nearly 61 000 spectators, a press-stand for about 250 reporters, and a photographers' stand for about 50 operators. It is in the form of a four-center oval, 300 by 500 ft. from face to face of the inner retaining walls, and about 750 by 930 ft. over all, covering an area of about 12½ acres.

The points to be observed in planning the structure were: large seating capacity; ample entrances, in order to avoid congestion at any point; strength and durability, with low cost both for construction and maintenance; and safety, especially for spectators. To meet these conditions, an excavation about 27½ ft. deep was made on the area required for a playing field, and the material thus obtained was used for building a surrounding embankment to a height of about 26 ft. above the general surface of the ground, its inner slope being continuous with that of the excavation.

* Presented at the meeting of November 15th, 1916.

The inner face of the slope, in excavation, was covered with reinforced concrete, built in the form of steps, on which were fastened benches for the spectators. A temporary wood facing, with benches, was built on the inner slope of the embankment, for use until the embankment had become consolidated. The outer slope was seeded with grass. Thirty reinforced concrete tunnels give access, through the embankment, to the spectators' seats; and two tunnels for the accommodation of the players, run directly to the field. The drainage from the playing field and the outer slopes of the embankment is taken by a sewer discharging into a river which runs near the Bowl.

The material was placed in the embankment in 6-in. layers, each thoroughly watered, and then rolled with two rollers, one grooved and the other smooth, one following in the track of the other. Drag-line scrapers, operated from 85-ft. towers running on a four-rail track laid outside the structure, and steam shovels, operating within the Bowl, were used, principally, for building the embankment. The shovels filled bottom-dump wagons which, with the teams of horses, were drawn up the slope by hoisting engines on the top of the embankment. Bottom, side-dump cars, and chutes were used for conveying the concrete from the mixers.

One of the special features of the construction is a cantilever retaining wall, 45½ ft. high, which forms one of the walls of the proposed gate-house.

History.

Football, the most popular of college athletic sports, though one of the oldest, is, under its new rules, one of the most modern of field sports. The first intercollegiate football match in the United States, between Yale and Harvard, was played in 1876, and Mr. Walter Camp, the so-called father of American football, is still one of the most valued advisors of Yale teams.

It was not until 1896, however, that the attendance at Yale games called for special accommodations for spectators at the intercollegiate matches. In that year, the Yale Athletic Association, to provide for any probable future demand for seats, built a stand to accommodate about 18 000 persons. Contrary to expectations, however, this stand soon proved inadequate to meet the demand for seats from those who desired to witness the "big" games, and additions to the stands were

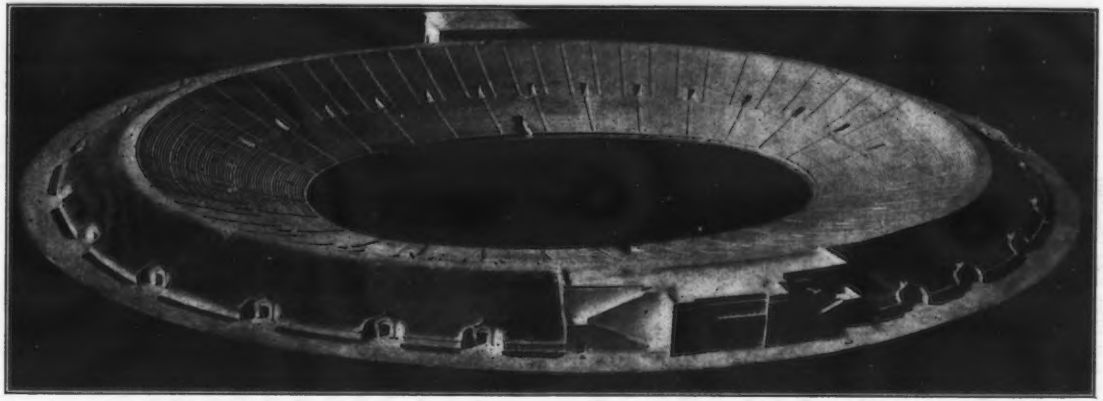

FIG. 1.—MODEL OF THE YALE BOWL.

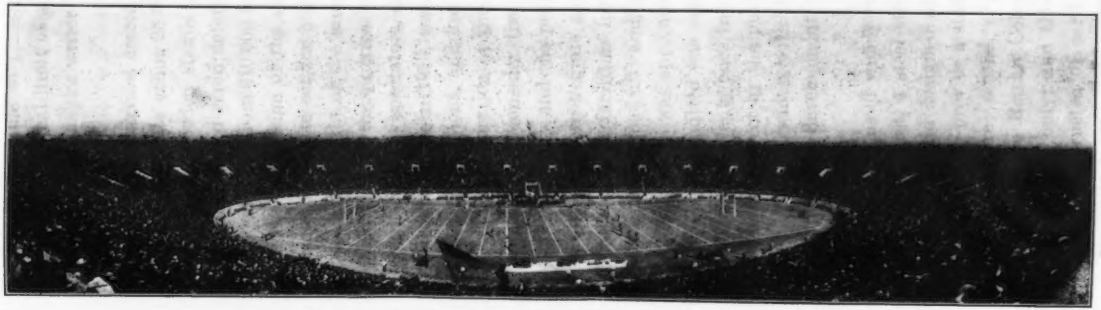

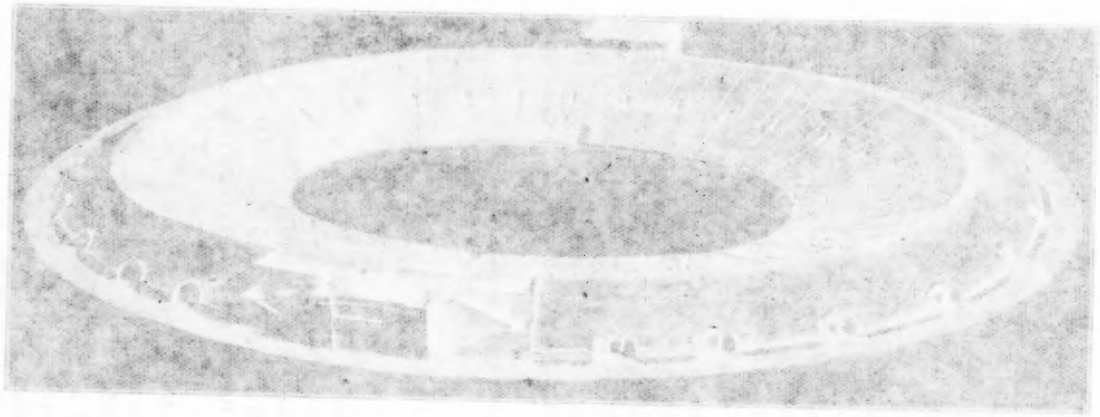

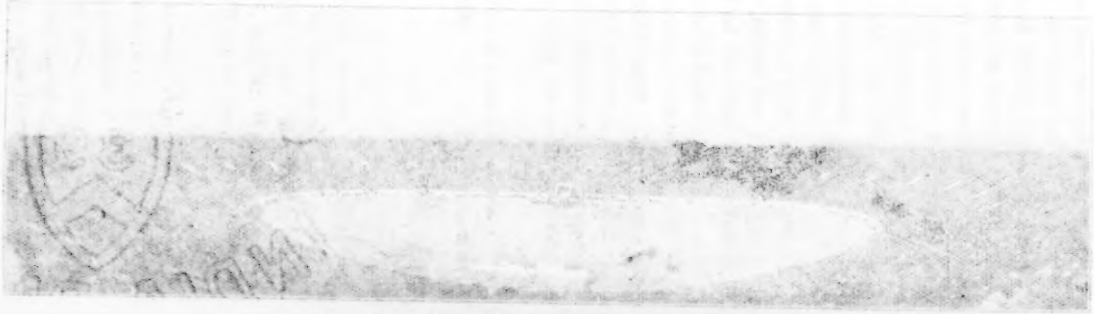

FIG. 2.—FIRST GAME IN THE YALE BOWL. YALE-HARVARD, 1914.

made from time to time until they finally contained 33 090 sittings and the practical limit of size for a stand in that location was reached. These, so far as the writer knows, were the largest wooden stands ever erected.

In 1904 Harvard erected its steel and reinforced concrete stadium, to accommodate about 23 000 spectators.

As the wooden stands at Yale were not painted, exposure to the weather caused rapid deterioration, and the annual expense for repairs amounted to from $10 000 to $12 000. In addition to this tax, the danger of the destruction of the stands, by fire or otherwise, immediately preceding the date set for a game, thereby necessitating its cancellation, and the thought of the much greater catastrophe of a fire occurring in them during the progress of a game, thereby creating a panic in the great crowd of spectators, caused much anxiety on the part of the management, and, in 1910, resulted in a movement to secure a permanent, more commodious, and fire-proof structure.

The Corporation of the University appointed a committee of seven graduates to consider the whole question of athletic development at the University and the provision of suitable accommodations for spectators at intercollegiate games. This committee recommended an increase in the facilities for out-door athletics, and the erection of a stadium for football; and, on its further recommendation, a committee of twenty-one was appointed to carry the latter into effect.

This committee was organized under the name of "The Yale Committee of Twenty-one, Incorporated", and began to carry its instructions into effect by the purchase of about 87 acres of land near the old athletic field, which, with the latter, gave a total area of about 110 acres available for development, divided into five separate fields by intersecting streets.

Three plans of widely varying type were suggested for the proposed stadium: First, a steel structure composed of separate units mounted on wheels and designed so that these units could be moved in such manner as to provide a stand for either football or baseball as necessity might require; second, a reinforced concrete structure based on the model of the Roman Colosseum, to seat 50 000 persons and designed for football only; and third, the plan suggested by the writer, for a stand constructed of earth faced with concrete, somewhat similar to reservoir construction, from which the idea was derived.

The first plan offered difficulties in the way of providing for suitably rigid foundations, on which the sections of the stand could be moved, without interfering with the playing fields; the second was prohibitive on account of its cost, which was estimated to be about $750 000. The third plan, offering as it did a stable, permanent, and fire-proof structure at a minimum of cost, both for construction and maintenance, was, as subsequently modified, adopted.

The plan as first presented was markedly different in shape from the Bowl as constructed, although the method of construction was the same. As first planned, it provided for football and baseball fields, with a quarter-mile running track, a 220-yd. straight-away track, and spaces for pole vaulting and jumping events, all surrounded by a single stand, an irregular heptagon in shape and of sufficient size to seat 50 000 persons. This stand was estimated to cost about $170 000.

Objection being made to having any part of the baseball field used for football and on account of the possible interference, in practice, by teams in different departments of athletics, the writer was requested to change the plans to provide for football only, and a structure, substantially on the lines of the present Bowl, was designed. This, for a seating capacity of 50 000, was estimated to cost about $235 000. In this plan the outer retaining wall and the tunnels, except the main tunnels to the field, were omitted, the entrances for the spectators being by steps leading over the top of the embankment. With the change in plans to provide for 60 000 spectators, the embankment became so high that tunnels for entrances became desirable, and this necessitated the erection of the outer retaining wall.

During the development of the plans, two questions were prominently raised concerning the probable stability of a concrete structure built on an earth slope varying from 1 on $2\frac{1}{2}$ to 1 on 4: First, whether expansion and contraction, due to temperature changes, and the heaving effects of frost in the underlying sand would not gradually move the concrete down the slope and, eventually, pile it in a disordered heap at the bottom; and second, whether material in the embankment could be compacted so solidly that subsequent settlement would not crack the concrete injuriously.

To answer the first of these questions so far as possible a few simple experiments were made regarding frost action. A sample of the sand was taken from the field within a few hours after a very heavy rain,

and it was found that only about 23% of the volume of the voids was filled with water, the total volume of the voids being about 37% of the volume of the sand when compacted. A bottle, about 10 in. in length and 1 in. in diameter, with a sharply contracted neck, was then filled with sand thoroughly compacted, and with sufficient water added to fill 23% of the voids. The mixture was then frozen, but no indication of any expansion of the mass was noticed. A similar experiment with 50% of the voids filled with water produced a like result. The experiment was then repeated with 75% of the voids filled, and the bottom of the bottle was cracked off.

To ascertain the extent to which water would be retained in the sand by capillary action, the bottle was filled with sand saturated with water. A piece of linen was then tied over the mouth of the bottle which was then reversed and the water allowed to drip. In 2 min. about 16% of the water had run out. The bottle was then set, mouth down, in a bed of sand, the broken off bottom being replaced in order to lessen evaporation from that end. After 24 hours 67% of the water had run out, and 80% at the end of 8 days. It was concluded, therefore, that, as the slope was to be entirely covered with concrete, thereby excluding all water except such as could pass through the expansion joints, the danger of any disintegrating effect resulting from frost in the underlying sand might be neglected.

As the steps were to be built in the form of horizontal arches, it was thought that these would take care of any possible movement due to temperature changes.

To provide for a possible settlement of the embankment, it was suggested that the steps be built in the form of reinforced concrete slabs, somewhat after the plan in the Harvard Stadium, supported on reinforced concrete girders resting on concrete piers built into the earth, the girders being raised a few inches above the face of the slope. Then, in case of any settlement, the girders could be shimmed up on the piers, and the structure restored to its original form. The estimated cost of this plan, however, proved to be so much in excess of that for concreting directly on the earth that it was abandoned, and it was decided to concrete first only the portion of the slope in excavation, and to provide the face of the embankment, temporarily, with a wooden superstructure, until such time as the embankment had ceased to settle.

Description.

The Bowl, as constructed, has a playing field, oval in plan, 300 by 500 ft., varying from a true ellipse by about 6 ft. at the point of greatest divergence, the radius of the sides being 420 ft. and that of the ends 120 ft.

The old wooden stands had been built with straight sides and ends, the corners being filled in with sections at 45° to these lines. The Har-

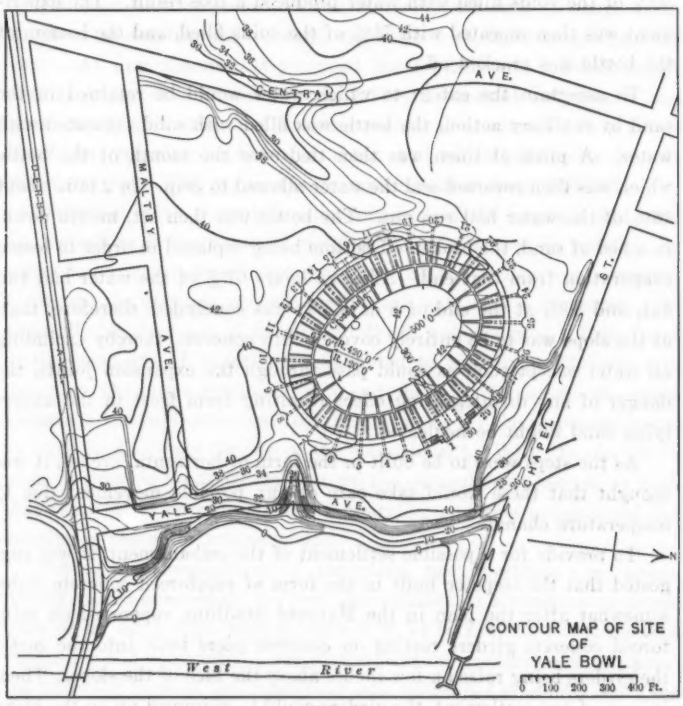

Fig. 3.

vard and Princeton Stadia have straight, parallel sides, joined by a curved section at one end, the other being left open. In such stands a person occupying a seat on a side near one end cannot get a good view of plays on the same side of the field near the opposite end. The oval form was adopted for the Bowl in order that all the spectators might have an unobstructed view of the plays in whatever part of the field

they might occur. This form also enables each spectator to obtain a view of the entire audience, a very thrilling spectacle when all the seats are filled and every one is roused to a high pitch of excitement by some brilliant play.

The space between the outer lines of the gridiron and the surrounding wall is of sufficient width to permit of a running track, 20 ft. wide and of a length only 200 ft. short of ¼ mile. As there was not room for a 220-yd. straight-away track—a feature which is considered necessary for an athletic field—without tunneling under the seating section, the track feature has been abandoned for the Bowl. The playing field is laid out so that the 5-yd. lines point toward the sun at 3 P. M. in the middle of November, the time when the principal match games are played, thus making the lighting of the two ends of the field the same.

The earth was scooped out over the area to be occupied by the playing field and piled up in an embankment surrounding it, the inner slope of the latter being continuous with that of the inner face of the excavation. The depth of the excavation was about 27½ ft. below the general surface of the ground, and the top of the embankment about 26 ft. above it, making the total elevation from the surface of the field to the top of the fill 53½ ft.

The inner face of the slope was graded to a smooth surface, with vertical as well as horizontal curves, to serve as a foundation for the sixty concrete steps. The tread of the steps is uniformly 30 in., with the exception of the step at the inner portal of the tunnels, which is 52 in. wide and is used as a cross-aisle. The bottom step is 4 ft. above the playing field, and the height of the steps increases uniformly by 0.006 ft. from the bottom riser, which is 8 in. high, to the top one, which is 12⅛ in. high.

The dishing shape, formed by this combination of vertical and horizontal curves, suggested the name "Bowl" which has been given to the structure, and provides advantages to the spectators for viewing proceedings on all parts of the field not possessed by any other large stand. The vertical curve gives a person occupying the top seat the same facility for seeing over the heads of the persons occupying the seats in front of him as that possessed by the spectators in the lower rows, the clearance being practically the same in all the rows of seats from a point about 200 ft. from the inner retaining wall.

FIG. 4.

The embankment is 15 ft. wide on the top in order to allow room for a promenade, 12½ ft. wide, back of the top row of seats, and then slopes down to a retaining wall, the top of which is 9 ft. above the surface of the ground outside the Bowl. This slope is 1 on 2, except opposite the portals, where it had to be steeper on account of the recessing of the portals into the embankment.

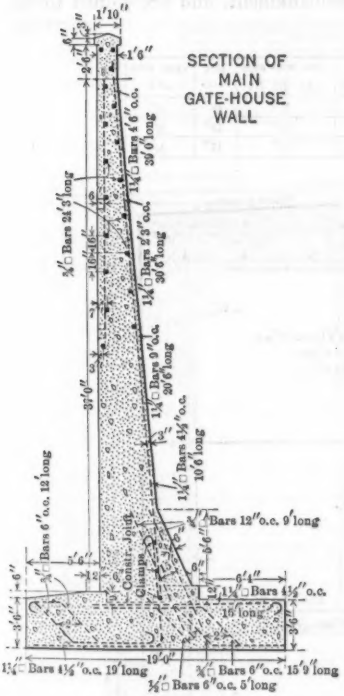

FIG. 5.

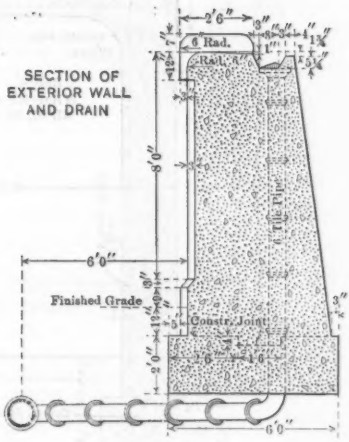

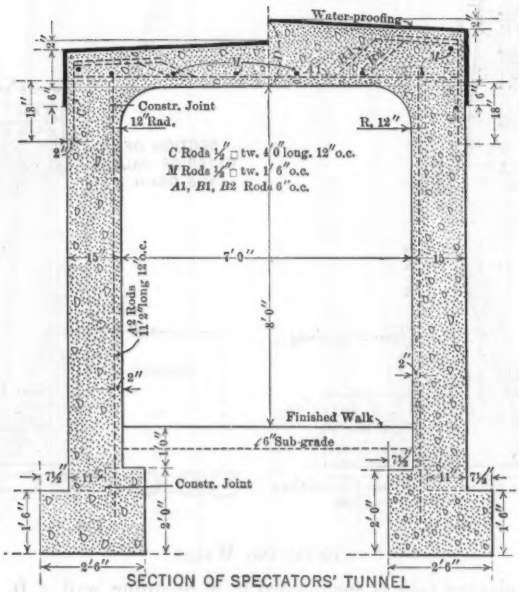

FIG. 6.

RETAINING WALLS.

The playing field is surrounded by a retaining wall, 4 ft. high, its top being level with the tread of the bottom step of the seating section. This wall is surmounted by a parapet which, with a 12-in. coping, is 27 in. high. The outer retaining wall is finished with a coping 12 in. thick, the front, top corner of which is rounded to a curve with a 6-in. radius, in order to render the wall more difficult to scale, in case any one de-

sired to take a short cut, financially, into the Bowl to witness a game. The pilasters project 3 in. from the face of the wall. They are carried up 6 in. above its top, and are finished with a cap 30 in. square over the front portion of the wall. For convenience in construction, both retaining walls were made as chords instead of arcs or circles, the angles being at the pilasters, which also serve as expansion joints. The outer portals are recessed 9 ft. into the embankment, and are joined to the main wall by curved wing-walls.

SECTION OF SPECTATORS' TUNNEL

FIG. 7.

TUNNELS.

Thirty tunnels through the embankment are provided as entrances to the amphitheater for spectators. These are all 7 ft. wide and 8 ft. high. They start from the level of the ground outside the Bowl and

terminate at the twenty-fifth row of seats from the bottom, where they are spaced uniformly along the cross-aisle. As the level of the ground opposite the main gate-house is 11 ft. lower than that on the opposite side, these tunnels are all on a slope, those on the westerly side being down toward the field on a maximum grade of 2.37%, and those on the easterly side up on a maximum grade of 4.18 per cent. The end tunnels have grades of 0.24 and 0.26%, respectively, just sufficient to afford good drainage.

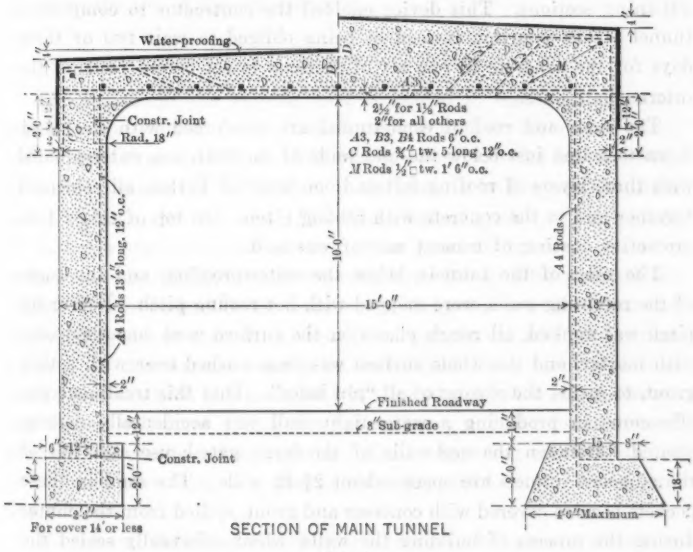

FIG. 8.

In addition to the thirty spectators' tunnels, there are two for the players, which can also be used as exits for the spectators. These run from the level of the ground outside the Bowl directly to the playing field. The one on the easterly side, 15 ft. wide and 10 ft. high, affords facilities for carting in loads of hay or straw, when necessary to protect the field from frost. It has a grade of 6.33 per cent. The other tunnel is 10 ft. wide and 8 ft. high. The difference in elevation between

the portals of this tunnel being too great to admit of a straight ramp for its entire length, a double flight of steps, with an intermediate platform 6 ft. wide, was built at the outer end and then a ramp, on a grade of 7.55%, for the remainder of the distance to the field.

The footings of the tunnels were all made monolithic, but the remaining portion was divided into lengths, not exceeding 30 ft., by expansion joints. Each joint was made by inserting in the side-wall forms steel plates bent to form a tongue and groove with flaring sides. On one side of these plates was placed a strip of tarred felt and, as the forms were filled, the plates were drawn up out of them, leaving the felt embedded in the concrete, thereby preventing the bonding of the adjoining sections. This device enabled the contractor to complete a tunnel at one pouring, instead of being obliged to wait two or three days for the concrete in one set of sections to set before pouring the intermediate ones.

The sides and roof of each tunnel are reinforced with steel and, down to a line just below the underside of the roof, are water-proofed with three layers of roofing felt and one layer of Tartex, all cemented together and to the concrete with roofing pitch. On top of this a 1-in. protective coating of cement mortar was laid.

The sides of the tunnels, below the water-proofing, and the backs of the retaining walls, were mopped with hot roofing pitch. Before the pitch was applied, all rough places on the surface were smoothed over with mortar, and the whole surface was then washed over with a thin grout, to insure the closing of all "pin holes". That this treatment was efficacious in producing a water-tight wall was accidentally demonstrated. Between the end-walls of the large gate-house and two of the adjacent tunnels are spaces about 2¾ ft. wide. The sand in these pockets became covered with concrete and grout, spilled from the chutes during the process of building the walls, which effectually sealed the interstices between the particles of sand, and rendered the pockets practically water-tight. Water from the roof of the tunnels ran into these pockets and, at one time, stood about 6 ft. deep without showing any signs of leakage or even sweating inside the tunnels.

The floor of each tunnel has a granolithic pavement. In the largest tunnel this is 8 in. thick; in all the others it is 6 in.

All the tunnels are well lighted by electricity, there being five 100-watt lamps in each of the spectators' tunnels and six in each of the

others. Hemispherical depressions were made in the ceiling, from which lamps project down into Holophane globes suspended from the under side of the roof.

Aisles.

An aisle, 52 in. wide, extends around the entire amphitheater at the inner portals of the tunnels. From this other aisles run down, opposite each portal, to give access to the lower twenty-five rows of seats, and a flight of steps leads from the lower end of each of these aisles to the playing field. Other aisles, one on each side of each spectators' tunnel, afford access to the upper thirty-five rows of seats and to the promenade on the top of the embankment.

Grading.

The surface of the playing field is graded to the form, approximately, of a segment of a football, the ground at the center being 1 ft. higher than that at the foot of the steps. On the narrow strip, 5 ft. wide, next to the retaining wall, the grade is broken so as to drain to the basins under the steps. The field was first graded to a sub-grade 18 in. below the established grade. Black loam, 16 in. deep, was then spread over the field in two layers, each layer being rolled with a 5-ton roller. Boston humus, 1 in. deep, was then spread over the loam and harrowed into it to a depth of about 3 in., and the entire area was then turfed. A thin layer—about $\frac{1}{2}$ in.—of sifted black loam was then spread over the turf, and grass seed was sowed and raked in. Although the turfing was done during the hot summer, and the foundation of the field was clean sand and gravel, judicious watering caused the grass to begin to grow and, in a few weeks, a firm field with a strong turf was obtained.

No sub-soil drains were laid under the field, as the material is very porous, and the level of the ground-water, as indicated by a well in the vicinity, is about 12 ft. below the surface of the field, thereby insuring good sub-soil drainage.

The outer slope of the embankment was brought to a sub-grade 10 in. below the established grade, and then filled with black loam. Strips of turf, 1 ft. wide, were then laid, 8 ft. apart, parallel to the edge of the promenade. The remainder of the slope was then seeded to grass. The strips of turf were intended to prevent the slope from gullying in

case of heavy rains before the grass was sufficiently grown to afford the necessary protection.

Besides the building of the embankment, there was a large amount of grading around the Bowl to make the grades of the surrounding grounds conform to the neighboring streets. In addition, Yale Avenue, a street about 1 500 ft. long and 80 ft. wide, was graded, the maximum cut being about 13 ft. The material from this grading, which was not required in the embankment, was used for filling about 11 acres of marsh, to a depth of about 3 ft., rendering it available as playing fields.

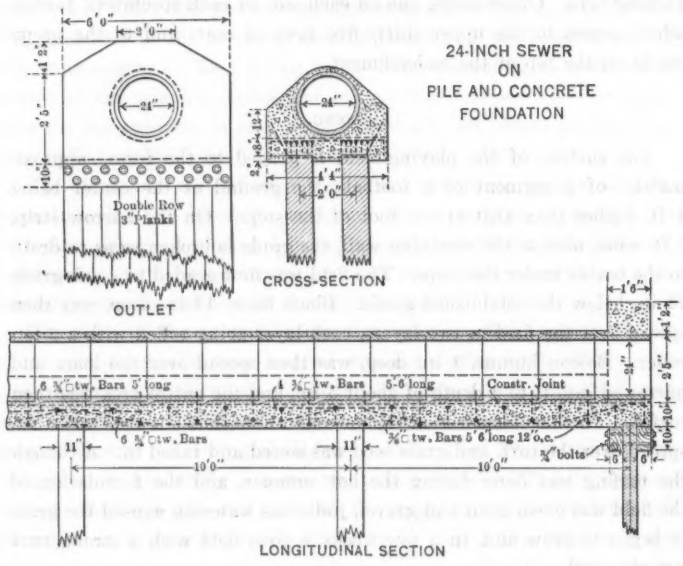

FIG. 9.

DRAINAGE.

The water falling on the inner slope of the amphitheater is caught in a gutter formed in the top of the retaining wall just in front of the first riser. This gutter is 6 in. wide, and varies in depth from 6 in. at the center of the panels to 9 in. at the aisles. It is covered with a galvanized cast-iron grating. Drain pipes, 6 in. in diameter, run from this gutter, through the wall, and discharge on slightly dishing slabs of concrete built under each of the flights of steps which lead from the aisles to the playing field. In the center of each of these slabs is a

small receiving basin, covered with a grating, which connects, by a 6-in. drain, with the drain which encircles the field. These basins also receive the drainage from the field.

JUNCTION MANHOLE OUTSIDE OF FIELD

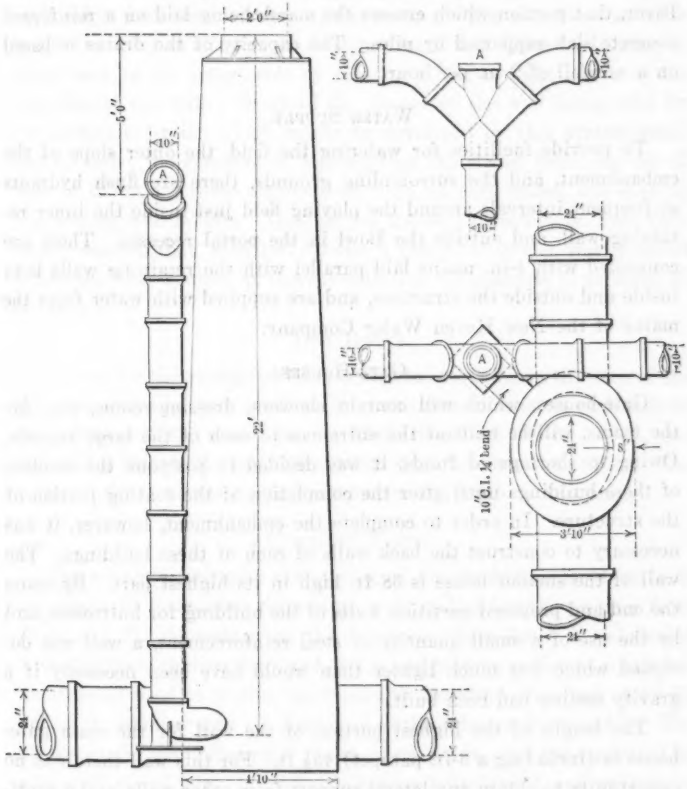

FIG. 10.

The water which falls on the outer slope of the embankment is collected in a gutter formed in the top of the retaining wall near the inner edge. This gutter is 9 in. wide and 6 in. deep, with flaring sides, to lessen the risk of the wall being cracked by ice, and is connected, at the lower end of each section, by a 6-in. drain with the drain which runs around the outside of the Bowl.

The field drain connects with a 24-in. pipe which runs under the main tunnel, and the drain which encircles the structure connects with the same conduit, by a drop-manhole, just outside the front wall of the proposed main gate-house. The main drain discharges into West River, that portion which crosses the marsh being laid on a reinforced concrete slab supported by piles. The capacity of the drains is based on a rainfall of 2 in. per hour.

Water Supply.

To provide facilities for watering the field, the outer slope of the embankment, and the surrounding grounds, there are flush hydrants at frequent intervals around the playing field just inside the inner retaining wall, and outside the Bowl in the portal recesses. These are connected with 4-in. mains laid parallel with the retaining walls both inside and outside the structure, and are supplied with water from the mains of the New Haven Water Company.

Gate-Houses.

Gate-houses, which will contain showers, dressing-rooms, etc., for the teams, will be built at the entrances to each of the large tunnels. Owing to shortage of funds, it was decided to postpone the erection of these buildings until after the completion of the seating portion of the structure. In order to complete the embankment, however, it was necessary to construct the back walls of each of these buildings. The wall of the smaller house is 38 ft. high in its highest part. By using the end and proposed partition walls of the building for buttresses, and by the use of a small quantity of steel reinforcement, a wall was designed which was much lighter than would have been necessary if a gravity section had been built.

The height of the highest portion of the wall for the main gate-house is (including a 3-ft. parapet) 45½ ft. For this wall there was no opportunity to obtain any lateral support from other walls, and a cantilever wall was constructed, this type being adopted in preference to a counterfort wall on account of convenience in placing and consolidating the back-filling, although, probably, the latter would have been somewhat cheaper. This is, so far as known to the writer, the highest wall of the cantilever type ever constructed.

The main reinforcing rods in this wall are 1¼ in. square. For the lower quarter of the height the rods are 3 in. apart on centers; for the

second quarter, 6 in.; for the third quarter, 12 in.; and for the top quarter, 24 in. As the wall was so high that it was impracticable to make these rods in single lengths and extend them down into the footing, they were made in two pieces with an allowance of fifty diameters for a splice just above the top of the footing. The rods were so large and the spacing so close at the bottom that it was deemed advisable to place them in the splice, side by side, on a line at right angles to the direction of the wall. To avoid the danger of the wall being split by the eccentric strains which might be developed by this arrangement, and to assist the concrete in transferring the strain from one set of rods to the other, three clamps were used on each splice, one each at top, bottom, and middle. Tests at the Mason Laboratory of Yale University showed that, with two clamps, a pull of 10 000 lb. was required before the rods would slip, thereby relieving the concrete of so much of its work.

Tool-Rooms.

Rooms for the storage of hose, tools, etc., required in the care of the field and grounds, were made in the embankment, one on each side of the approach to the main tunnel. These rooms are 24½ by 12½ ft., and of varying height, the concrete seating steps forming the ceiling. The entrance doors to the rooms open on the approach to the tunnel.

Concrete Facing.

The concrete facing on the portion of the amphitheater which is in cut was built in sections three steps wide and of lengths varying from 3½ to 17½ ft., depending on the location. Each block is reinforced with steel in both directions and at top and bottom, sufficient reinforcement being used to permit the blocks to sustain a live load of 50 lb. per sq. ft., whether they are supported at the sides, ends, or middle. The blocks, at the circumferential joints, overlap 3 in. and are separated by a layer of tarred felt. All radial joints are butt-jointed, and were given a coat of roofing pitch, to prevent the bonding of the blocks, but in the middle joint in each panel there was inserted a layer of Elastite, ⅜ in. thick, to provide for expansion.

The facing was built in alternate blocks, laid checker-board fashion, 3 days being allowed for the setting of the concrete in one set of blocks before the intermediate ones were laid. The blocks forming the aisles were laid last, as they were the shortest. The slabs were all 7 in. thick

Fig. 11.

in the thinnest part, under the junction of the tread with the riser. In addition to the regular reinforcement, a strip of wire lath, 6 in. wide, was built into each of the aisle steps, ½ in. below the surface, in order to prevent the spalling of the corners of the steps.

To prevent the glare from such a large surface of concrete, if left in its natural color, and to afford variety of coloring, the facing was made a dark slate by the addition of 1 lb. of lampblack to each barrel of cement used in the granolithic surfacing. The inner retaining wall was left in the natural color of the concrete.

Wood Facing.

The wood facing, on the slope of the embankment, consists of 2 by 6-in. sills, laid radially not more than 4 ft. apart. To these were spiked triangular-shaped blocks, 3 in. thick and 18 in. long on the upper edge, for supporting the tread of the steps, which are 18 in. wide, the remainder of the 30-in. space allowed for each row of seats being left uncovered. Although this left the earth slope exposed to the elements, the material in the embankment is so porous and absorbs water so readily that little trouble has been experienced from washing of the embankment.

Seats.

The permanent seats built on the concrete facing consist of 2 by 10-in. planks, with the upper side planed to a curved surface, supported on galvanized-steel standards anchored to the concrete. These standards were made in four different sizes, in order to fit the varying height of the risers and make the height of the seat within the limits of 17¾ and 18¼ in. The back rest is a 1¼ by 5-in. board, with the front face curved and the corners rounded, supported by 2½ by 2½-in. wooden standards bolted to the backs of the steel ones. The wood for the permanent benches is rift-sawed Douglas fir from Oregon. U-shaped Tobin bronze bolts were specified for anchoring the steel standards to the concrete, but a lower price being offered by the contractor for Sherardized-steel anchor-bolts, the first benches erected were anchored with them, but, as these proved to be not well adapted for the purpose, their use was abandoned, and about two-thirds of the seats are fastened with the bronze bolts as originally planned.

The temporary benches on the wood facing consist of 1¼ by 10-in. spruce boards supported by 2 by 12-in. wood standards spiked to the

sills. These benches are provided with back rests of the same kind as the permanent seats.

A minimum spacing of 17¾ in., with an average of a little more than 18 in. was allowed for each sitting. With this spacing there are 60 617 seats for spectators.

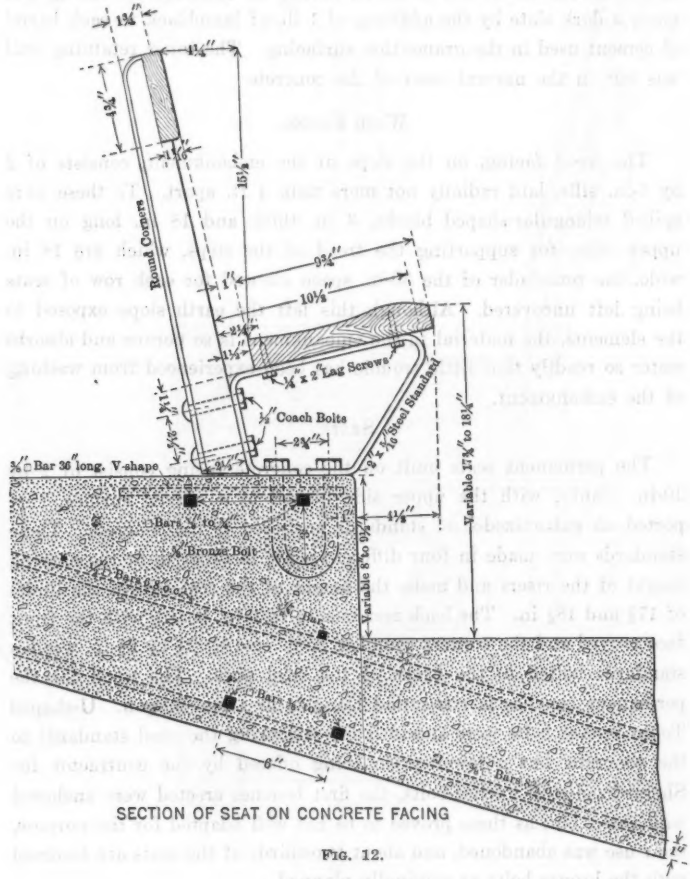

FIG. 12.

PRESS-STAND.

A stand for the representatives of the Press was erected on the westerly side of the Bowl, just below the top of the embankment.

This is provided with two rows of seats, and shelves for convenience in writing or telegraphing. With a spacing of 21 in., this stand will accommodate 249 persons, sitting. In addition to this, there is pro-

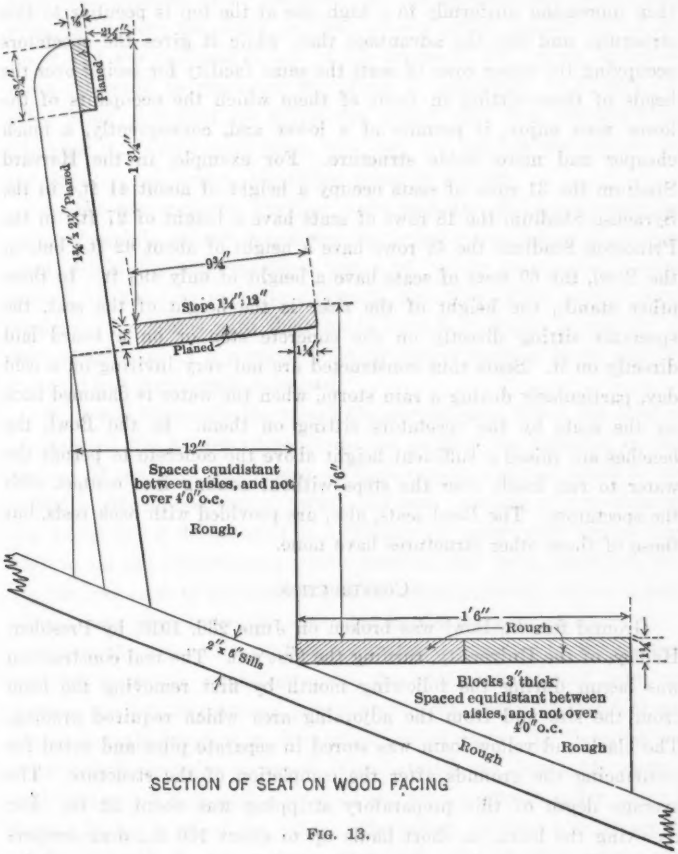

FIG. 13.

vision for three rows of persons, standing, giving accommodations for about 400 additional, or a total of about 650 in the press-stand. Back of the press-stand, and raised a little above it, a stand for photographers will accommodate about 50 operators.

Peculiarity of Seating Arrangements.

The seating arrangements in the Bowl are noticeably different from those in other large stands, such as the Harvard, Princeton, and Syracuse Stadia. The plan of having a low riser for the bottom step and then increasing uniformly to a high one at the top is peculiar to this structure, and has the advantage that, while it gives the spectators occupying the upper rows of seats the same facility for seeing over the heads of those sitting in front of them which the occupants of the lower rows enjoy, it permits of a lower and, consequently, a much cheaper and more stable structure. For example, in the Harvard Stadium the 31 rows of seats occupy a height of about 41 ft.; in the Syracuse Stadium the 18 rows of seats have a height of 27 ft.; in the Princeton Stadium the 48 rows have a height of about 62 ft.; but, in the Bowl, the 60 rows of seats have a height of only 49½ ft. In these other stands, the height of the riser is the height of the seat, the spectator sitting directly on the concrete step or on a board laid directly on it. Seats thus constructed are not very inviting on a cold day, particularly during a rain storm, when the water is dammed back on the seats by the spectators sitting on them. In the Bowl, the benches are raised a sufficient height above the concrete to permit the water to run freely over the steps without coming into contact with the spectators. The Bowl seats, also, are provided with back rests, but those of these other structures have none.

Construction.

Ground for the Bowl was broken on June 23d, 1913, by President Hadley, of the University, turning the first sod. The real construction was begun during the following month by first removing the loam from the site and from the adjoining area which required grading. The black and yellow loam was stored in separate piles and saved for resurfacing the grounds after the completion of the structure. The average depth of this preparatory stripping was about 22 in. For removing the loam, on short hauls up to about 100 ft., drag-scrapers were used; on hauls from about 100 to 250 ft., wheel scrapers; and for long hauls, bottom-dump wagons.

Several plans for placing the material in the embankment were considered by the contractor, but the one finally adopted for handling the greater part of it was the use of two drag-line scrapers running on

adjustable cables and operated from two towers, 85 ft. high, by two 12 by 16-in. double-drum engines, supplied with steam from two 125-h.p. locomotive boilers. The towers ran on a four-rail elliptical track laid around the outside of the Bowl. One end of the carrying cable was fastened to a "deadman" on the opposite side of the field from the tower; the other end ran over a pulley at the top of the tower and was fastened to one of the drums of the engine, by which means it could be regulated for filling or emptying the bucket, the cable being slackened for filling the scraper and then tightened for dumping it. The second drum was used for hauling the scraper up the slope; it ran back to the filling point by gravity.

As the two scrapers, working night and day, did not remove the material rapidly enough to indicate the probable completion of the contract within the time specified, two ¾-yd. rotary steam shovels were started, in order to expedite the work, and these filled bottom-dump wagons. The teams with their loads were then drawn to the top of the embankment by a portable hoisting engine working there, and the material was distributed as desired.

As it was impracticable to roll the embankment below the level of the tops of the tunnels, dependence for packing the material in this portion of the work was placed on such consolidation as could be obtained by the liberal use of water, and such tamping as was done by the teams being driven over it. Streams of water were always kept playing on the embankment where material was being deposited, and the portions next to the tunnels and the retaining walls were generally sluiced into place from piles deposited by the teams or scrapers.

Above the tops of the tunnels, the material deposited by the scrapers was left in ridges extending across the embankment; that from the wagons was left in scattered piles; in each case sufficient material was placed to make layers 6 in. deep when leveled down. The leveling was done with horse-drawn scrapers. The material was thoroughly watered and then rolled, first with a grooved and then a smooth roller, one following in the track of the other. The rollers weighed 800 lb. per ft. of length, and, by using them alternately, the effective weight was practically doubled. Each roller was drawn by four horses, and each passed four times over the entire area being rolled. The embankment was kept about 1 ft. wider than the theoretical lines in order to insure the compacting of the material out to the edges of the finished fill.

To ascertain the settlement in the embankment, after its completion thirty-one benches were established around the top. Each bench consisted of a mass of concrete in which was inserted a ½-in. square steel rod, placed about 4 ft. below the surface, the end of the rod terminating a few inches below the surface. Levels taken on these benches have shown that, after a lapse of 2 years, the average settlement has been only about ¼ in., and the maximum settlement at any bench about ½ in. About one-half of this settlement occurred within the first month after the establishment of the benches.

A comparison of the volume of the embankment with that of the excavation shows that the material in the former is nearly 7% more dense than that of the natural bank. It is probable, therefore, that the slight settlement which occurred was caused by the compression of the underlying material, due to the added weight of the fill, rather than by any subsequent consolidation of the embankment itself.

The favorable results obtained in securing a solid embankment were probably due to the character of the material of which it is composed and the method of placing it. The material was sand and gravel, almost entirely free from clay, loam, or other substance which would retain water. By the alternate use of the two kinds of roller, not only was a downward pressure exerted, but, at the same time, a lateral motion was given to the particles of sand, thereby tending to bring them into close contact with one another.

Water for sprinkling the embankment and mixing concrete was obtained from a group of driven wells at the foot of the bluff, at the edge of the marsh, and was distributed by a 4-in. pipe, laid around the outside of the Bowl, with hose connections at frequent intervals. The water from the wells was pumped by a single-acting, triplex pump, operated by an electric motor. The contractor was required to furnish at least 150 gal. of water per min., and this quantity was delivered continuously, day and night, including Sundays and holidays, while the embankment was under construction. A connection was also made with the mains of the New Haven Water Company, in order to insure a constant supply in case of a failure of the wells or a break down of the machinery.

As the drag-line scrapers left the inner face of the slope in a very irregular condition—a series of deep gullies and sharp ridges—the contractor devised a leveling scraper for smoothing up the work. This

consisted of a frame, about 6 ft. square, of 12 by 12-in. timbers, the front faces of which were shod with steel plates. This frame was attached to the drag-line by a bridle, and was drawn up the slope in the same manner as the excavating scrapers. The final trimming of the slope was done by hand shoveling.

Two mixers were used for supplying concrete for the tunnels. For the footings, there was a portable, ½-yd., gasoline mixer at the inner portal of each tunnel. This delivered its material into cars running on a track laid between the footings, from which the concrete could be dumped into the forms on either side as desired. An electrically operated ¾-yd. mixer near the center of the field was used for mixing the concrete for the portion of the tunnels above the footings. The concrete was conveyed on cars running on an industrial railway track laid on the ground from this mixer to a point near the inner portal of the tunnels, then up an inclined trestle to their top and then on timbers laid on the side forms. From the mixer to the foot of the incline the cars were hauled by a horse, and for the remainder of the distance by a hoisting engine outside the Bowl.

For building the outside retaining wall and the smaller gate-house walls, there were two ½-yd. mixers on an elevated trestle built on the site of the gate-house. These delivered the concrete into bottom, side-dump cars running on an industrial railway laid on top of the wall forms. For the large gate-house walls, a mixing plant was established near the wall, and the concrete was delivered into a 120-ft. elevator, from which it was distributed by chutes. The same plant also made the concrete for the inner retaining wall and the facing steps. For this work the concrete was delivered by the chutes into the bottom, side-dump cars running on a portable track laid just above the inner portals of the tunnels; from them it was distributed, by portable chutes laid on the ground, directly into the forms, the slope of the bank being steep enough to cause the concrete to flow in the chutes. The greatest distance through which concrete was carried by the chutes, in a single run, was about 250 ft.

For handling sand and stone at the two main mixing plants, elevated bins were constructed so that cars or trucks could be run on top of them and deliver material without shoveling. Chutes at the bottom of the bins delivered material into cars which were divided by partitions to hold the required quantity of each ingredient for one

batch. From the cars the materials were dumped directly into the mixer.

All the sand for the work was obtained at the site. Though an abundance of gravel, of a size suitable for the concrete, was found in the excavation, only a small quantity of it was used in some of the footings, as it contained a considerable proportion of sandstone pebbles which it was feared would absorb moisture and disintegrate under the action of frost if exposed to the elements. Most of the stone used was crushed trap rock. This was brought from a quarry about 2½ miles distant by two motor trucks: a 5-ton truck which not only carried its own load but also hauled 3 tons in a trailer; and a 3-ton truck. The price paid for hauling the stone was 27 cents per ton.

The cement used in the work was furnished by the contractor, but was paid for as a separate item, thereby enabling the engineer to change the proportions of the ingredients in the concrete, as seemed desirable, without causing any dispute as to the quantity used. The cement was all tested at the mill by agents of testing laboratories.

Comparison with Other Stadia.

The Bowl is believed to have the largest seating capacity of any structure of the kind in existence, and to have been exceeded by only one of ancient times—the Circus Maximus of Rome, which is stated to have seated 380 000 persons. Statements regarding the capacity of the Roman Colosseum, the most widely known of the ancient amphitheaters, vary widely from 45 000 to 100 000. It is stated that in the ancient amphitheaters only the classes were provided with seats, the masses being obliged to stand.

With the seats removed, the Bowl could accommodate comfortably a standing audience of about 125 000. The Athens Stadium seated 50 000; the stadium of the College of the City of New York seats about 10 000; the Syracuse and Tacoma Stadia each accommodate about 20 000; the Boston baseball stands, 24 000; the double-deck stands at the New York Polo Grounds, about 28 000; the Harvard Stadium, as first constructed, seated 23 000, but, with additions and with temporary seats at the open end, it can accommodate about 45 000; the new Princeton Stadium seats about 41 500; and the Bowl about 61 000.

Though the Bowl is the largest of the modern stands, it is also, probably, the cheapest per sitting. Though the actual cost of other

stands is not accurately known, the contract price, as reported in engineering and other journals, gives the average cost per sitting as ranging from about $36.00 for the stadium of the College of the City of New York down to about $8.50 for the Princeton Stadium. The cost per sitting for the Bowl, as constructed, including the grading of the grounds around it, was about $7.35. The cheapness of the Bowl was partly due to the exceptionally favorable conditions at the site for building this kind of a structure. This was a level plain elevated about 40 ft. above a marsh from which it was separated by a steep bluff, thus affording perfect drainage at a minimum of expense. The material was clean sand and gravel extending to an unknown depth, easy to handle, and ideal for making a solid embankment.

Previous to the building of the Bowl, the materials used in the construction of grand-stands were wood, steel, reinforced concrete, or a combination of the two latter, and, in the case of ancient structures, masonry. Though wood is a suitable material for stands of small size, it is entirely unsuited for large ones, owing to rapid deterioration when exposed to the weather and liability to destruction by fire. Though monumental structures of masonry, like the Roman Colosseum, were possible with the slave labor available in the first centuries of the Christian era, it would be impracticable to finance such an undertaking at the present time. Steel and reinforced concrete are, from an engineering standpoint, more practical building materials for structures of this kind.

Maintenance charges are an important factor to be considered in planning for a steel stand of large size. Whether temperature changes and frost action will injuriously affect skeleton structures of the size of the large modern stadia, when built of reinforced concrete, either alone or in combination with external steel, is an interesting question yet to be answered. Apparently, the only portions of the Bowl which will require material expense for maintenance are the benches, as the remainder of the structure is practically a portion of the earth's crust—a low hill surrounding a small valley.

One advantage of this form of construction, besides its cheapness, is the facility with which the plastic materials, earth and concrete, may be adapted to the formation of curved shapes, thus, without any material expense, permitting of curved instead of straight sides, which were such an objectionable feature of the old wooden stands at Yale.

Another advantage is that a stand can be increased in size without materially affecting any part of the work already done. By building a balcony over the promenade and the portion of the seats above the tunnel portals, the seating capacity of the Bowl can be increased to about 100 000 without affecting any portion of the structure other than by the removal and replacing of a few blocks of concrete to permit the building of proper footings for columns, the embankment being sufficiently stable for the support of the additional structure.

With nearly 61 000 seats for spectators provided, it was thought the stand would be large enough to meet any possible demand for accommodations from those interested in football, but when the time limit expired for the receipt of applications for tickets for the first game in the Bowl—Yale *vs.* Harvard in 1914—it was found that more than 80 000 had been received. To meet this demand, so far as possible, extra seats were erected over the promenade, so that the number of people who witnessed that game was probably a little more than 70 000. In spite of this vast number, in 12 min. from the close of the game, the Bowl was practically empty of people, and this time might have been shortened by about 5 min. had not the spectators tarried to witness the celebration of the victory, on the gridiron, by the partisans of the winning team. Although the Bowl was emptied in such a short time, there was no congestion at any point except in the aisles, as the capacity of the tunnels to handle the crowd was greater than that of the aisles, and the thirty-two tunnels distributed the crowd over such a large area, the inner circumference of which was a little more than ½ mile, the distance around the outside of the Bowl, that there was plenty of room for the free movement of the people.

Adaptation for Other Purposes.

Although the Bowl was built for football alone, its remarkable acoustic properties render it admirably fitted for the production of dramatic events on a large scale, and two such have already been held there with pronounced success: the Greek play, "Iphigenia in Taurus", given by Mr. Granville Barker under the auspices of the Yale Dramatic Association, and the opera "Die Walküre", by the Metropolitan Opera Company, under the auspices of the Yale School of Music. For these performances, the stage was erected near the center of the field, and a

section of about 25 000 seats was set apart for the spectators at one end of the amphitheater.

To celebrate the two-hundredth anniversary of the removal of Yale College to New Haven, a pageant is now being prepared in which it is expected that about 8 000 performers will participate.

Under favorable atmospheric conditions, when there are only a few people in the Bowl, a whisper spoken at the center of the field can be distinctly heard at the tunnel portals; and a conversation, in an ordinary tone of voice, can be carried on between persons stationed on opposite sides of the amphitheater. At the performances mentioned, even the softest passages could be plainly heard in the most remote seats reserved for spectators. With the seats removed, a person with a good voice and accustomed to public speaking could, undoubtedly, address an audience of 125 000 and be heard distinctly by every one.

The following are some of the principal items of construction:

Earthwork	331 000	cu. yd.
Mass concrete	16 000	" "
Concrete facing	111 000	sq. ft.
Wood facing	145 000	" "
Granolithic pavement	35 000	" "
Cement	26 000	bbl.
Steel for reinforcement	482	tons.
Wood benches	18	miles.
Turf laid	161 000	sq. ft.
Sewers	6 400	lin. ft.
Water mains	4 700	" "
Area covered by structure, about	12½	acres.

The Bowl was built by the Yale Committee of Twenty-one, Incorporated, Mr. Thomas DeWitt Cuyler, Chairman, with Mr. David Daggett, Chairman of the Structures Committee. Edward G. Williams, M. Am. Soc. C. E., was Advisory Engineer, and Mr. Donn Barber, Consulting Architect. The writer was the Designer and Engineer in charge of construction. Mr. Joseph H. Mulvey was Chief Inspector. James B. French, M. Am. Soc. C. E., served as Consulting Engineer for a few months at the beginning of the work, and Thomas C. Atwood, M. Am. Soc. C. E., as Construction Manager for a few months at the end. The Sperry Engineering Company, of New Haven, Conn., was the contractor for the whole work.

DISCUSSION

Mr. Atwood.

THOMAS C. ATWOOD,* M. AM. SOC. C. E.—As has been stated in the paper, the Yale Bowl is the largest structure of its kind which has ever been built. When compared with the designs for other stadia proposed for this place, its simplicity and effectiveness at once command attention. The character of the structure, essentially of earthwork, ensures its permanence; and its safety from fire and accident is beyond question.

The original sketches called for a structure, the estimated cost of which was somewhat less than $400 000, but the several engineers and architects engaged on the work have advised certain changes, affecting the appearance and permanence of the structure, which have nearly doubled this cost.

The paper is hardly fair to other stadia in stating the cost of the Bowl as $7.35 per seat, this being the cost in its present incomplete condition. When finally completed the cost will be about $750 000, or approximately $12.30 per seat, or considerably more than the cost of the Princeton Stadium. This includes the cost of completing the concrete lining of the Bowl and placing the permanent seats, the gate-houses, permanent toilet facilities, and permanent fence. The Princeton Stadium is not fully completed, the wooden seats being lacking, but the final cost will probably not be more than $10 per seat. Of course, the difference in size must be taken into account, and a larger structure of the Princeton type would undoubtedly cost more per seat. All things considered, it is probable that the Bowl is the more economical structure for the location, which is ideal for its type, and for the size demanded.

There is no doubt that the shape of the Bowl, with its curved sides, is far better than the regular stadium U-shape with straight sides. It is this horizontal curve of the sides, rather than the vertical curve produced by making the height of each riser uniformly greater than that of the one next below it, which enables the rise per seat to be small, the straight-sided structures requiring more rise in order that spectators may see all parts of the field. The importance of this is seen when it is realized that in the Bowl only 20 000 of the seats are enclosed between the goal lines extended, and that more than 40 000 are at the ends, back of the goal lines. At Princeton about 16 000 seats lie between the goal lines, and 25 000 are back of them, but only one end is enclosed, the other being open.

Of the problems in connection with the Bowl, few were of less interest than the eleventh-hour proposition to put in a track and provide a 220-yd. straight-away course by tunneling at one end. Careful

* New Haven, Conn.

Mr. Atwood.

estimates showed that this would involve such heavy construction that the cost would be about $50 000, and would detract considerably from the appearance of the Bowl. Experience with such tunnels, as at Syracuse, N. Y., has shown that the running conditions are not satisfactory; and, as the Committee had plenty of land available, and as an ideal track on open ground, together with a permanent stand to seat 10 000 people—as many as are likely to attend the intercollegiate track events—would cost little if any more than the tunnel, it was decided to complete the Bowl as planned and build a track and stand later.

Referring to the general construction: when the speaker was placed in charge, on January 1st, 1914, approximately one-third of the work had been completed, and the embankment had reached the top of most of the tunnels. As noted in the paper, the rolling could not be carried on between the tunnels, and it seemed improbable that the bank had been thoroughly consolidated at all points, so the top of the bank was leveled up, divided into sections, and flooded, holes being drilled down through it at the same time by iron bars or water jets about 8 ft. apart, on centers, both ways. At some points no settlement could be observed, but at others there was considerable. On this uniformly compacted base the remainder of the bank was built, as described in the paper, and with gratifying results.

The whole settlement of the completed bank is not shown by the bench-marks noted in the paper, as these were not set until the bank had been completed for nearly 2 months, but there is no doubt that the settlement was very small compared with that found in other carefully built banks, such as those under aqueducts.

The water pipe entering the Bowl was carried through the main tunnel in a small trench in the concrete floor, so that a break could not affect the foundations of this tunnel and the embankment.

The turf strips, noted as being placed in the outside loam slope, were very successful in preventing deep wash, as was shown by a torrential rain which occurred before the seeded area had started to grow, the water in no case getting under the sod, and no gullies more than 3 in. deep being formed.

The high reinforced concrete retaining wall mentioned has performed its work well, a movement outward at the top of little more than ½ in. being the greatest noted, or corresponding to a settlement at the toe of the wall of only about ⅛ in. Relative to this matter, it may be mentioned that claim for royalty on account of the Bone patent has been made within the past year, and the speaker has done considerable work in investigating this, with the aid of searches made in the Library of the Society, and has some references to walls, built before the date of the patent, which are not included in the summary of this subject contained in *Engineering News*.

Mr. Atwood.

In the concrete facing inside the Bowl, the horizontal arching action was not made use of, dependence being placed on the interior retaining wall to care for any possible tendency of the blocks to slide down hill.

The lampblack placed in the mortar for the top of the facing blocks aided materially in giving them uniformity of color, as the sand used contained uncertain quantities of iron which caused some of the concrete to have a pinkish hue.

The aisles were given a top dressing of Trus-Con floor hardener, and no wear is yet perceptible; but it is difficult to say whether or not this is due to the hardener. This hardener should be applied with care by skilled men, as a few blocks, which apparently got an overdose, have turned rusty.

The inner retaining wall and the tunnel portals inside the Bowl were originally planned to have pipe-rail fences, but this was changed to heavy concrete parapet walls, at a considerable saving in cost and with a decided improvement in the appearance of the Bowl, the general idea of massive simplicity being carried out more fully.

The design of the permanent seats was another interesting problem. As finally worked out by Mr. Everard Thompson, Assistant Secretary of the Committee, and the speaker, the seat was placed on the edge of the step and supported on a steel bracket or standard which allows full play for wind and water, so that the structure can be cleaned with comparative ease.

The lumber for these seats was selected with great care. It was desirable to use edge grain lumber, and investigation showed that this could be obtained in only three woods, Douglas fir, redwood, and Western hemlock and Noble fir classed together. As redwood is likely to stain clothing when wet, and Western hemlock could not be obtained in sufficient quantities, Douglas fir was chosen.

Time was of great importance, and some doubts were expressed as to the possibility of getting the lumber in the 3 months available. The order was given by the speaker on August 18th, and the first carload arrived on September 29th, just 6 weeks later. When the order was given, the lumber was in the log. It was sawed, kiln-dried, planed, and shipped within 2 weeks, and was 4 weeks on the road. The kiln-drying, in this case, was preferred to open-air drying, as it boiled out the pitch pockets in the fir. All the lumber is vertical grain, clear and free from knots or other defects, except an occasional pitch pocket.

Another interesting matter was the design of the playing field. The underlying sand was so porous that a stream from a 2-in. hose would all disappear within 2 or 3 ft. of the end of the hose, so the problem was to retain moisture enough to prevent the grass from burning out, and yet have a field that would dry quickly after a rain. This was accomplished by using 18 in. of black loam and by crowning the field 1 ft., the cross-section consisting of two very flat curves, convex upward,

joined by a sharper curve at the center of the field. The scheme has worked perfectly. Mr. Atwood.

The summary of items of construction given is for the Bowl in its present state, and, of course, many of these will be changed when the work is completed.

In order to assist any one desirous of obtaining further information, the following bibliography of articles on the Bowl, all of which are illustrated, is given:

Engineering Record, Unsigned articles in March and November, 1914.

Engineering News, Article by the speaker, November 12th, 1914.

Yale Alumni Weekly, Article by the speaker, November 27th, 1914.

Proceedings, Connecticut Society of Civil Engineers for 1915. Paper by the author.

Journal, Boston Society of Civil Engineers, June, 1916. Paper by the speaker.

Much credit is due to the Committee of Consulting Engineers which assisted in getting the work properly started. This Committee consisted of Professor John C. Tracy, of Sheffield Scientific School, and H. C. Keith and James B. French, Members, Am. Soc. C. E. Later, Mr. French was appointed Consulting Engineer in charge of the design and construction of the work, and the first contract was prepared under his direction.

The credit for carrying on the remainder of the work is largely due to Edward G. Williams, M. Am. Soc. C. E., who served his Alma Mater without pay in the capacity of Advisory Engineer, and by his wise advice and careful supervision brought the work to a successful conclusion. The architectural features of the Bowl were designed by the Consulting Architect, Mr. Donn Barber, of New York City, and are exceptionally effective.

The three contracts covering the work described were finally concluded early in 1915. The speaker, however, was retained by the Committee to carry on the engineering work, and contracts were prepared covering the completion of the seating structure, permanent toilet buildings, and permanent fences, in expectation of proceeding soon with this construction. This expectation was abandoned in the spring of 1916, and the only work now being done is the construction of some 17 000 temporary seats for the Yale-Harvard game, on November 25th, 1916. This will make the total seating capacity of the Bowl on that date 77 189.

J. B. FRENCH,* M. AM. SOC. C. E.—The speaker can most properly speak for those who advised against building the concrete facing directly on the embankment. Professor John C. Tracy, of Mr. French.

* New York City.

Mr. French. the Yale Faculty, H. C. Keith, M. Am. Soc. C. E., and the speaker were asked to report on this question in November, 1912. Plans submitted to this Committee at that time were materially different from those followed in the construction. As described in the papers then submitted, the surface of the inner slope was to be cut into steps and faced with concrete 4½ in. in thickness, laid directly on the sand, in the same manner as concrete curbs and sidewalks are built. No steel reinforcement was proposed, and all drainage was to be carried from the top of the embankment down over all the steps to the level of the playing field. At this time, also, it was hoped that the Bowl could be completed in the fall of 1913. In other words, it was proposed to build a continuous concrete lining, nowhere more than 4½ in. thick, to cover an area measured in acres, on a new and hurriedly built embankment 27½ ft. high. It was the opinion of the Committee that, in a structure as important and conspicuous as this was bound to be, the procedure proposed would invite undesirable defects, and that, though it might be possible to compact the embankment so that unsightly cracks might not occur, it was preferable to reduce the risk to a minimum. The Committee, therefore, though approving the general plan, reported adversely to the proposed construction of the concrete lining, and recommended a lining, lifted a few inches above the ground, made up of inverted channel-shaped slabs, supported by radial girders resting on small pedestals built in the embankment. It was proposed to make the slabs uniformly 30 in. wide, of the same cross-section, and to lay out the work so that both slabs and girders should have spans of about 20 ft., and, to the greatest extent possible, be duplicates of each other. The variation in the rise of the steps or benches was to be taken care of by the form of the tops of the radial girders. It was planned to have the very large number of slabs required cast in advance in a concrete casting yard, where the concrete work could proceed independently during the progress of the earthwork, and to erect the pre-cast units very quickly with a small traveling derrick as fast as the embankment was completed.

To facilitate the construction, and at the same time take care of the rainfall on the inner lining, the slabs were not to fit each other closely, but were to be separated by slits at least ½ in. in width and were to be tilted to shed water. Rainfall was to be prevented from accumulating, and was to be allowed to escape directly through the sand and gravel, as it had always done before in the plateau in which the structure was to be built. The ability of this material to absorb rainfall had been proved to the satisfaction of the Committee by sinking a shaft at the site from the surface of the ground to below the depth of the playing field, and this shaft had cleared itself of water immediately after every heavy rainfall. To protect the newly made inner

face of the earth structure from being carried down by the drainage, it was proposed to cover it with a layer of cinders, about 6 in. thick, a method found particularly effective in the construction of railroad embankments. Mr. French.

The Committee obtained estimates on the construction described from contractors most experienced in such work, and was convinced that the cost of the completed structure would not be increased materially by the proposed changes from the original plan.

The recommendations of the Committee were formally adopted; detailed plans and specifications were prepared and accepted; and a contract was executed for the earthwork and concrete tunnels, leaving the slab work for the interior lining to be included in a later contract. At this stage, however, other counsel prevailed, and the slab and pedestal plan was abandoned. From the description given in the paper, it appears, however, that when the time arrived for actually building the concrete lining on the embankment, notwithstanding the extremely careful and expensive methods used to compact the fill, it was not deemed wise to disregard the advice originally given, and the construction of the permanent lining was postponed until the danger of settlement should be known to have passed. It is also to be noted that the temporary construction finally placed on the embankment allows the rainfall to pass directly into the underlying sand and gravel without accumulation, exactly as was proposed in the slab and pedestal plan.

In view of the final decision, not to build directly on the embankment, it seems unfortunate that so much expense was incurred in compacting the material, as this will now be done by several years of exposure to the elements.

It is the opinion of the speaker, and he knows it to be the opinion of others who have had experience in building railroad embankments, that the rolling of clean sand and gravel, such as was available for this work, is of doubtful advantage, and, on the other hand, that the liberal use of water while the material is being deposited is highly effective. From the levels reported by the author, it seems to have been demonstrated that the fill was well compacted, but it does not seem at all clear that this result was due, to any great extent, to rolling. As the paper states, the very considerable part of the embankment between the tunnels was not rolled, and as, in addition to the water applied while the material was being deposited, the bulk of the fill had been exposed to a winter of snow and rain, the actual advantage of the rolling does not seem to have been very conclusively demonstrated.

H. C. KEITH,* M. AM. SOC. C. E.—What the speaker is inclined to say is not so much in discussion of the paper as an expression of Mr. Keith.

* New York City.

Mr. Keith. appreciation of the great idea which Mr. Ferry presented to the world in building the stadium in this form, and in this way, at New Haven. There are very few places where such a stadium could be built satisfactorily: the nature of the soil and the location with respect to the possibilities of drainage were great factors in making this a possibility.

Although it was necessary for the speaker and his associates on the Board of Consulting Engineers, at one time, to differ from Mr. Ferry in his recommendations in some details, yet they always felt that he was deserving of great credit for the plan presented. The method of construction has also been an important factor in making the design a success.

It is disappointing that the paper gives no information as to the cost of the stadium as it is finished to-day; it is hoped that before it is printed in its final form, such figures will be included. It is well that the *Transactions* of the Society should make ample record of this construction.

Mr. Dunham. H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—The double rolling, with frequent disturbance of the material, was helpful in some degree in making a firm embankment. Experience has shown the advantage of vibration in solidifying sand and gravel when under pressure. Those who have had occasion to direct the tamping of loose sand and gravel for railway water tanks and building foundations will be apt to agree in this. The vibration in all such cases, even when slight, is more effective than the pressure. This was well illustrated by experiments made a few years ago in New York City by Mr. Alfred O. Crozier in compacting sand for concrete products. The almost instant reduction in volume and hardening of the mass that occurred under slight vibration in two directions and without any pressure except the weight of the material itself was a matter of surprise and interest to all observers. In the writer's opinion, any easily operated tamping machine, even if heavy blows are not delivered, would be more effective than the rollers. This view is not to be considered as a criticism of this excellent paper, which brings distinction to its author.

Mr. Hitt. HENRY C. HITT,† ASSOC. M. AM. SOC. C. E. (by letter).—The writer has been very much interested in this particularly well written description of an unusual piece of construction. The author has given a very complete and satisfactory description, full of the data one wants, of the details of the design and of the construction methods.

The design certainly appears to be very successful. The "bowl" shape is an outdoor adaptation of old principles of auditorium design, and undoubtedly provides the most ideal seating scheme, as well as being architecturally beautiful. It is strange that it has not been

* New York City.

† Seattle, Wash.

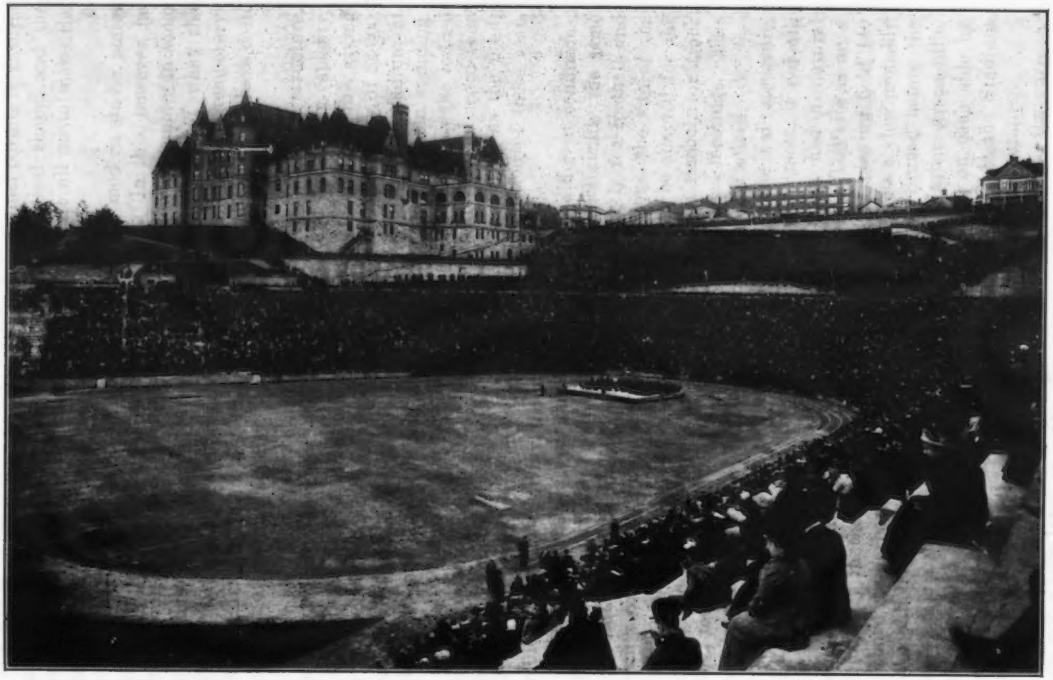

FIG. 14.—THE TACOMA STADIUM.

used more frequently with other stadia. The slate-colored concrete, with a trim of the inner retaining wall and the tunnel portals in natural color, the comfortable seats, the beautiful elliptical shape, and the careful orientation as to the afternoon sun, must all go to make the structure a credit to every one responsible. Mr. Hitt.

The author, in comparing the Bowl with other modern stadia, states that it is probably the cheapest per sitting unit. In this, however, he is in error, as the Tacoma Stadium, which the Bowl resembles in some ways, has cost, completely equipped, only about 85% of what the Bowl, in its unfinished condition, with a portion of the seats temporary, and the dressing rooms not built, is reported by the author to have cost, per unit of seating capacity.

Thus far, the total cost, of every kind, of the Tacoma structure, built in 1910, has been $147 000, and an estimate of the seating capacity, based on the same assumptions as used by the author, is 23 784, giving a unit cost of $6.20. The architects claim a seating capacity of 32 000, and more than 35 000 people have actually occupied the stadium at one time, with none of them on the field, but part of them standing.

The site has also a reserve capacity of about 15 000, as the sodded terraces rise for 43 ft. above the top of the seats around more than half the perimeter, at a proper slope for future seating as the needs of the rapidly growing city demand it. The addition of these seats would materially cut down the unit cost of the whole.

The two structures were designed to fill widely different conditions, but are similar in the result. The fields are of practically the same area, but where the Yale Bowl was designed strictly for football and seating capacity, with few or no limiting conditions, the site of the Tacoma Stadium was limited, and the field had to be adapted for the general use of the people and the adjoining High School, for track work, football, baseball, pageants, concerts, or political meetings. This made a complicated problem, which was most happily solved.

The seating scheme is similar to one end only of the Yale structure, with every occupant able to see the whole field, and most, if not all, the audience. At Tacoma, however, the designers had a natural location, of which they took the fullest advantage. The site is on a promontory in the very heart of the city, with the playing field 140 ft. above the harbor. From the Stadium seats one gets a view probably not equalled by that from any similar structure. Spread before the spectator is a magnificent sweep of busy Tacoma Harbor, green hills. and snow-clad mountains. The Stadium is flanked on each side by beautiful buildings rising above the seats, on one side the Stadium High School and on the other the State Historical Museum.

Although the site was naturally somewhat adapted to the purpose, there was a very large quantity of excavation, more per unit of seating

Mr. Hitt. capacity than with the Yale Bowl, and about two-thirds of it proved to be very hard cemented gravel. All the seats are carried on columns and radial girders about 20 ft. apart, the risers of the seats, 3½ in. thick, reinforced with a structural frame carrying the seat load between the girders. Part of the columns, at the outer end, are carried on piling, and part of the field at this end is a fill of 147 ft., but there has been no trouble from settlement.

Twenty-eight arc-light projectors are placed around the field above the seats, and twelve more are suspended by cables, high above the field, affording ample light for evening performances. The acoustics are very fine, and concerts have been entirely successful. The stadium is fully equipped with dressing rooms, and comfort stations for the spectators.

The principal quantities were, approximately:

Earthwork	185 000 cu. yd.
Reinforced concrete	10 000 cu. yd.
Reinforcing steel	160 tons, plus
Clinton fabric	130 000 sq. ft.
Area of field	3.6 acres

The Tacoma Stadium was built by the Tacoma School Board, Mr. Frederick Heath having been the architect, and Mr. L. A. Nicholson the engineer.

Mr. Lynch. ALEXANDER S. LYNCH,* ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Ferry states that Sherardized bolts were first used to fasten the seats to the concrete and then abandoned for the bronze bolts, as originally planned. He does not state why this change was made, other than that the Sherardized bolts were unsatisfactory. The writer would like to know why they were unsatisfactory.

Mr. Atwood states that the greatest movement in the high walls was ½ in. A recent examination of the walls shows that the movement in one was less than ¼ in., and in the other it was ¾ in., making a noticeable and very unsightly crack. The writer would like to ask if the soil under both walls was the same, or if there was a difference in the design of the walls.

The final cost of the bowl as given by Mr. Atwood is $750 000. Does this include the cost of the 23 000 seats erected for the Harvard games of 1914 and 1916, and subsequently removed?

There seems to have been no apparent reason for applying Trus-Con floor hardener to the aisles. Mr. Atwood states that no wear is perceptible. Neither is any wear perceptible in the floors of the tunnels, although the traffic there is much greater. There was no more reason for applying Trus-Con hardener to the aisles of the Bowl than for apply-

* West Haven, Conn.

ing it to the concrete sidewalk. The only effect now noticeable is that the hardener was improperly applied, leaving many of the blocks a dirty, rusty brown, unpleasant to look at, and spoiling the general soft gray tone produced by the use of lampblack. Mr. Lynch.

After reading Mr. Atwood's discussion, one is led to wonder why Mr. Ferry should have submitted a paper on the Bowl. Mr. Atwood gives "much credit" to the Committee of Consulting Engineers, which assisted in getting the work "properly started", and to others, but nowhere does he mention Mr. Ferry, except to refer to a paper read by him before the Connecticut Society of Civil Engineers. The writer, like hundreds of other engineers throughout the country, was under the impression that Mr. Ferry had not only designed the Bowl, but that he had in truth created "something new under the sun." The writer still holds that belief.

CHARLES A. FERRY,* M. AM. SOC. C. E. (by letter).—In reference to the cost of the Bowl, Mr. Atwood states: "when finally completed the cost will be about $750 000, or approximately $12.30 per seat." He does not give the details of this estimate, further than to state the different pieces of work required to complete the structure. Of these, the plans for the "permanent toilets" and the "permanent fence" have not been finally settled, so far as the writer knows; consequently, the cost might be any sum that Mr. Atwood chose to assume. It is questionable whether the cost of a fence enclosing the Bowl should be charged to that structure any more than that of the land on which it is built. Mr. Ferry.

The sum paid to the contractor was a little less than $448 000. The plans for the Bowl were radically changed after the work was well advanced, as mentioned by Mr. French, thereby necessitating much extra work, as well as extra prices for considerable work already under contract. This also included a large sum for grading, which, although desirable in the development of the plans for the athletic field, was not necessary in the construction of the Bowl itself. It also included the cost of the temporary dressing rooms and the erection and removal of the temporary toilets and extra temporary seats for the Yale-Harvard game of 1914. If the extra temporary seats built for the Yale-Harvard games are to be included in the cost of the Bowl, as apparently they have been in Mr. Atwood's estimate, then, in all fairness, their number should be included in computing the cost per seat. On this basis, that cost would be only about $9.70 per seat, even at the extravagant estimate of $750 000.

The writer is confident that if the Bowl had been built as originally planned by him, the cost of the completed structure, including that of permanent toilets, which was not included in the original esti-

* New Haven, Conn.

Mr. Ferry.

mate, would not have exceeded $450 000, or about $7.40 per seat, as the contractor's bid, based on the engineer's list of quantities, was lower than the writer's estimate made on the same basis.

This price compares favorably with that quoted by Mr. Hitt for the Tacoma Stadium, namely, $6.20, when the relative sizes of the two structures are taken into account, as the price per seat increases with the increase in size of the structure, regardless of the materials used.

Judging from Fig. 14, illustrating Mr. Hitt's admirable discussion, benches are not provided in the Tacoma Stadium, the spectators sitting directly on the concrete, as in the Harvard and Princeton Stadia. The permanent benches for the Bowl cost about $0.93 per seat, including painting.

The cost of the Tacoma Stadium would seem to confirm the writer's opinion that large stands constructed in the manner used by him in building the Bowl are more economical than those built by any other method hitherto used.

The history of this structure well illustrates the truth of the old adage that "too many cooks spoil the broth." Only, in this case, the "broth" (Bowl) was not spoiled, but the "high cost of living" (building) was very largely increased.

The writer is exceedingly skeptical regarding the utility of Mr. Atwood's method of consolidating the embankment, as described by him. No levels were taken on the embankment at the time, and, as there were no near-by permanent objects with which to compare the height of the embankment, the measurement of the settlement was dependent on the imagination of the observer. To believe that a given quantity of water, discharged at the bottom of small holes, 2 or 3 ft. deep and about 8 ft. apart (assuming that such holes existed in the saturated sand after the pipes or bars were withdrawn), would have any more effect in consolidating material several feet below the bottom of the holes, than an equal quantity percolating uniformly through the full depth of the sand, requires more credulity than is possessed by the writer.

As for the effect on the upper portion of the embankment by jetting water down into it, the writer is positive that the result was just the opposite of that desired. The water injected into the embankment washed out the finer particles of sand and deposited them in flat, volcano-like cones around the pipe, and the coarser particles were left in as loose a condition as it was possible to make them by the boiling action of the water escaping upward around the pipe. Only about one-half the circumference of the Bowl was treated by this novel method of "consolidating" material; and the opinion that this work was not only useless, but worse, would appear to be substantiated by

the fact that the benches which showed the greatest subsequent settlement were in the sections thus treated, and the points of least settlement were in those portions which did not receive the "water cure", although the latter were on the west side of the Bowl where the depth of fill, between tunnels, was greatest, the tunnels on the east side being largely in cut. Mr. Ferry.

Mr. Atwood states that:

"In the concrete facing inside the Bowl, the horizontal arching action was not made use of, dependence being placed on the interior retaining wall to care for any possible tendency of the blocks to slide down hill."

The writer has never had any fears that the concrete blocks would slide down hill, particularly those near the foot of the incline, where the slope is only about 1 on 4, unless pushed down by those near the top, where it is about 1 on 2½. If, however, there ever should be any such tendency to slide, he has much more faith in the resistance due to the arch action than in that of the inner retaining wall, for the concrete steps abut against the thin lip of the gutter formed in the top of this wall, and, although the lip is reinforced, the pressure required to shear it off is, probably, only a small fraction of that which would be required to crush or buckle the concrete facing under arch action. At the present time, 2½ years after the laying of the concrete on the lower part of the slope, there are no indications that there has been any sliding of the blocks down hill.

The experience of the past 2 years indicates the wisdom of the Committee in abandoning the plan for an open concrete facing raised above the embankment, as described by Mr. French, and in re-adopting the plan for a tight facing laid directly on the earth, as recommended by the Advisory Engineer, Mr. Williams.

Although the material of which the embankment is composed is very porous and readily absorbs the water from an ordinary rainstorm, it does not take care of that from heavy downpours, such as are likely to occur several times a year. Thus far, there has not been much trouble from the gullying of the inner face of the embankment, as the runs between the seats are in contact with the ground, thus forming water-breaks every 30 in. Nevertheless, after a very heavy rainstorm, the care-takers are obliged to shovel sand from the runs and fill up the gullies which have formed between them. If gullies, 3 or 4 in. in depth, will form in one storm when there are water-breaks every 30 in., it is reasonable to suppose that serious ones, such as might undermine the concrete footings, would form in a period of a few years when the water had an unobstructed run of 150 ft., even though the slope was covered with a layer of cinders.

Mr. Ferry. The principal point in controversy between the writer and the engineers consulted by the Committee previous to the adoption of the plans, was whether the material in the embankment could be consolidated so that there would be no settlement which would be likely to cause injurious cracking of the concrete facing. The writer's 20 years' experience in back-filling sewer trenches and, particularly, in the construction of an embankment on which to build a slow sand filter, led him to believe that it was possible, by the use of water, supplemented by thorough rolling, to construct a stable one for the Bowl. For the filter foundation, the maximum depth of the fill was about 16 ft. The material composing the fill was a mixture of clayey hardpan and a very fine sand saturated with water—practically quicksand. These materials were mixed roughly by working both borrow-pits at the same time, but there was no special effort to secure a thorough mix by harrowing. No water was used, except such as was contained in the quicksand and from occasional rains. The material was leveled off in layers about 8 in. in thickness, and was thoroughly rolled with a grooved roller; a smooth roller was not used. The fill was completed late in the fall. Benches were established at various points, after which an embankment, about 18 in. high, was built around the edges of the fill, and the area was flooded with water, the pond being maintained throughout the winter. In the spring, the water was drawn off, the benches were tested, and it was found that the maximum settlement was about $\frac{1}{8}$ in., a little better result than was obtained at the Bowl, although, at the latter, the depth of fill was nearly twice as great as at the filter foundation.

The argument advanced by Mr. French, that because "the bulk of the fill had been exposed to a winter of snow and rain, the actual advantage of the rolling does not seem to have been conclusively demonstrated," does not apply to the section of the embankment, about 300 ft. in length, in the vicinity of the proposed large gate-house.

A portion of this fill, that immediately back of the retaining wall, is more than 40 ft. in depth (the deepest fill on the work) and all of it, from foundation to promenade, was deposited in the 9 weeks between April 4th and June 6th. The material was consolidated only by the use of water and rolling, as specified for the remainder of the work, the assistance rendered by Nature, in the form of snow and rain, being negligible, as the water secured in this way was insignificant in quantity in comparison with that applied artificially. The average settlement of this portion of the embankment, in the 2 years following its completion, was less than $\frac{3}{8}$ in.

The writer believes that any one who observed the action of the moistened sand under the rollers would readily admit that they performed a very important part in the consolidation of the material.

Mr. Ferry.

The height of the ridges formed by the grooved roller was noticeably less with each successive passage of that machine; and the use of the two kinds of roller, passing alternately, was much more effective than that of either a smooth or grooved one alone would have been.

The Sherardized bolts, referred to by Mr. Lynch, were lag-screws between the threads of which was spun a flat wire spiral to serve as reinforcement in transmitting the thrust from the screw to the concrete.

These bolts were mechanically defective in two respects. The wire spiral was likely to become slightly bent or sprung, in which case, only one thread of the screw would have a bearing, thus reducing the effective strength of the fastening. The defect which gave the most trouble, however, was caused by the machine which fashioned the bolt. This machine, in gripping the rod, changed the shape of the shank of the bolt, making the cross-section slightly oval instead of round, and, in addition, it formed a slight ridge along the sides of the shank along the major axis. The result was that, when the bolt was being unscrewed, it acted as a wedge which split a spall, several inches long, from the face of the step, thereby releasing the bolt. The only way in which this could be avoided was to give the bolt one or two turns just after the concrete had taken its initial set, thus forming a hole large enough to permit the bolt to be turned. If it was not turned until after the concrete had become hard, the head twisted off.

To repair the damage, dove-tailed recesses were chiseled into the steps, and the bolts were re-set in mortar. Several hundred bolts had to be re-set in this way before the writer succeeded in getting an order to discontinue their use.

In order to insure the head of the bolt having a firm bearing on the standards, the bolts were set about $\frac{1}{4}$ in. lower than the position they were expected to occupy finally. In spite of this precaution, however, the concrete broken off in unscrewing the bolts filled up the holes to such an extent that it was impossible, in many cases, to screw the bolts down again to a bearing, and it was necessary to drill out the holes and blow out the dust with a blast from an air pump, the threads of the screw interfering with the use of a spoon.

In the writer's opinion, whenever it is necessary to use screws for attaching fixtures to concrete it should be done by building the bolt into the concrete, rather than the reverse. If, however, it is desirable that the bolt shall be the movable piece, then the nut should be in an enclosing shell, thereby preventing the thread of the screw from coming into contact with the concrete. Several hundred bolts of this type were used, with entire satisfaction, for fastening the Holophane globes to the ceiling of the tunnels.

The difference in the movement of the two walls, to which Mr. Lynch calls attention, was undoubtedly due to a change in the design

Mr. Ferry.

of the structure, rather than to any difference in the foundation, as that is of the same general character throughout the field.

The material at the field consisted of strata, of sand and gravel, of varying thicknesses. Among these were three or four layers of a very fine, compact sand—material which would be quicksand if in contact with water. One of these strata, about 6 in. thick, occurred about 3½ ft. below the base of the high retaining walls, and was uncovered in excavating for the foundation of the adjacent tunnels. The construction manager expressed grave fears that, unless the foundation of the wall was carried down through this stratum and built on the coarse sand beneath it, the wall would slip. As this stratum was about 20 ft. above the level of ground-water, and as no water could reach it from above after the embankment was concreted, there was no danger of the sand becoming "quick"; therefore the writer believed that, to support the wall, this material was equal to, if not better than, the coarse but less compact sand beneath it, and he strongly objected to the expenditure of the several hundred dollars necessary to extend the footing as proposed. In spite of his protest, however, the extra footing was built under one wall, the forms for the other wall having been erected and the steel placed in position before Mr. Atwood became connected with the work. This extra footing, under the outer edge of the base of the T-shaped wall, was built in the form of the frustum of a wedge, with the narrow edge down, thus reducing the effective bearing area of the sand about one-half, the sides of the wedge having comparatively little supporting value. This is the wall which Mr. Lynch refers to as having moved ¾ in. The companion wall, at the other end of the gate-house, which he says has moved less than ¼ in. is the same in all respects, except that it is 1 ft. higher, thereby sustaining that much additional pressure, but is built with a flat base, as planned originally.

Paper No. 1387

CONTROL OF THE COLORADO RIVER AS RELATED TO THE PROTECTION OF IMPERIAL VALLEY*

By J. C. Allison, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. L. Sonderegger, J. A. Ockerson, and J. C. Allison.

Synopsis.

The general problems involved in the control of the Colorado River and the conservation of its waters for irrigation have already been treated exhaustively in papers and discussions before the Society, and it is not the intent of the writer to reopen the subject for purposes of debate. In this paper the direct relation of river control to the maintenance and ultimate perfection of levee systems protecting Imperial Valley, California, is the fundamental topic, as it has been the phase of the subject with which the writer necessarily has been most concerned.

In a broad sense, the problem of excluding the Colorado's overflow from the Valley has been solved. The maintenance of existing lines of defense, and the establishment of exterior auxiliary or supporting lines, may be considered as matters of detail. Final and complete protection, making possible the reclamation and beneficial use of all the arable lands of the delta, is to be secured, in the opinion which the writer holds in common with other engineers acquainted with the

* Presented at the meeting of September 6th, 1916.

situation, most satisfactorily by forcing the river back into the bed that it abandoned in 1910, and keeping it there with impregnable retaining works.

Methods of accomplishing that feat have been discussed, and estimates of cost have been made by several engineers, but methods and estimates have been based on emergency closures of breaks of the Colorado which, the writer believes, do not necessarily govern the case. Immediate protection being afforded by lines of defense which may be maintained with no difficulty and at small cost, the restoration of the river to its old channel is no longer an urgent need, and does not call for emergency methods. A favorable time may be chosen for the work, and methods less expensive than those heretofore considered may be applied.

It is safe to assume that engineers generally know the situation of Imperial Valley in relation to the Colorado, and only a brief statement of the problems presented to operators of the irrigation system will be necessary. The slope of the Valley from sea level at the Mexican boundary line is northward to the Salton Sea, 280 ft. below sea level. About 25 miles south of the line is the highest land in the delta, the elevation of which, before the change in the river's course, was 34 ft. above sea level at the westward end of the delta cone. The normal elevation of the river bed at the canal intake is about 100 ft. above sea level.

In flood season, which reaches the maximum in June, the river overflows the delta south of the crest of the delta cone, and fills a shallow sink at the west end known as Volcano Lake. The most rapid fall is southward, and the flood-waters find their way to the Gulf of California through Hardy's Colorado, which drains Volcano Lake; but the cone is so flat that some of the flood-waters normally spill from the lake northward into what was a shallow drainage channel known as the New River.

In 1905 the river broke through its bank north of the delta cone, or "Paredones" crest, and flooded the north slope of the delta. In draining off the inundated land to the Salton Sink, the water cut deep gorges in New River and in another drainage channel on the east side of the Valley, known as the Alamo. In the event of another incursion of the river, the gorges would carry the water, and there would be no inundation of farm lands on the American side. If per-

mitted to flow for any great length of time, the flood in the New River gorge would cut back the grade, and in time the recession would reach the old channel and lower the bed below the level of the intake, so that no water could be diverted into the main canal. Therefore the menace to Imperial Valley of an unchecked break would be drought, not inundation.

The problem presented by the change of course of the river through the delta in 1910, following the drainage channel known as Bee River to Volcano Lake, and thence through the Hardy, was the prevention of a northward flow into New River. That problem was solved by building the Volcano Lake levee, and by extending the Paredones levee of the California Development Company, parallel with the Bee River.

A deposit of silt raises the bed of Volcano Lake and consequently the surface elevation of the overflow water, and that has been met by increasing the height and cross-section of the levee. A small break in the levee in 1914 allowed some of the overflow water to go northward, but it was diverted easily from the head of New River gorge and turned into New River at a point where it did not produce any dangerous recession of grade.

Interior Lines of Defense.

North of the levee paralleling Bee River, which is now the main Colorado, interior lines of defense exist, and may be strengthened and extended very readily. The Inter-California Railroad grade serves as a barrier, and it may be connected with the Volcano levee. The function of interior lines would be to intercept and divert to the west a shallow body of overflow water having no defined channel and no eroding velocities. Numerous canal banks also serve as auxiliaries to check velocities and turn the water westward, where it may be taken care of readily.

The effect of one of these canal banks on the overflow of 1914 suggests a third line of defense and a method of diverting any water that might pass the Paredones and Volcano levees. This canal is the New Alamo Mocho, constructed by a rancher in Mexico to irrigate a large tract lying on both sides of New River channel. The water that came through the levee break, about 6 000 sec-ft., spread over the ground in a wide, shallow sheet, and was held by the canal bank, along which it flowed slowly to the west.

Assuming a breach in the Volcano Lake levee to be closed promptly, the inflow northward would be cut off before the slowly spreading sheet of water reached the west end of the proposed Alamo Mocho Canal bank, and it might not be necessary to let the water into New River at all. The overflow could be impounded and used as a reservoir for the West Side Main until drained off.

Each year prior to the break of 1905-06, which eroded the bed of New River, the overflow water from the Colorado entered on the northern slope of the divide. Each year this flow to the north subsided of its own accord, before the flow of the water to the south. The interior line of defense cuts off the water from entering New River gorge and so reinstates former conditions.

As an interior line of protection in emergency arising through possible failure of the primary lines, this proposed extension of the Alamo Mocho bank as a diverting levee seems entirely feasible and comparatively inexpensive to construct and maintain. It is important that the run-off channels leading southward from Volcano Lake be kept open and free from obstruction. Bee River has now cut a defined channel for itself through the silted Volcano Lake, and may be expected to keep to that approximate course for a long time.

Primary Line of Defense.

Only through negligence and failure to maintain the old California Development Company levee from Hanlon Heading south could the river again get into the region that was flooded in 1905-06, and be a menace to the Alamo Canal and delivery structures. The existing levee, properly maintained and protected from destruction by erosion of the banks of the river, is sufficient protection to the canal system as far as it extends. In 1914 a breach at the point where the levee bends to the southward resulted from negligence. Erosion of the river bank threatened the levee two years before the breach occurred.

The danger could have been averted by inexpensive means, but responsibility for the maintenance of the levee was a matter of controversy, and nothing was done until the bank and a point of the levee had been cut away by the river. Much money was wasted in an attempt to close the breach by the trestle and rock fill method on the line of the original location. The attempt was a complete failure, and the simple expedient of building a levee around the break was

adopted, and the damage was readily repaired. In this case there was no danger of destructive flooding, as the river did not overflow the banks, and there was no head of water against the levee. The breach was caused by erosion of the bank and levee which could have been prevented by temporarily diverting the current away from the bank with jetties, until rock revetment at the toe of the levee could be placed.

The breach at "House 7", as the point is designated, was not due to any defect in the location or construction of the primary line of defense, but solely to failure to maintain the line. It was an administrative, not an engineering failure.

During the flood of 1914, the long stretch of bank between the levee and the river was cut away, up to the toe of the levee, but the latter was saved intact by dumping large quantities of rock at the foot of the slope, which filled the trench scoured by the current, and formed permanent revetment. A railroad track on the levee, and an inexhaustible supply of rock in a quarry at Hanlon Heading, near by, facilitated this method of revetment.

To make this line of defense impregnable, it is necessary only to reinforce the levee wherever bank cutting occurs, doing the work from year to year as conditions call for it. Assuming that reasonable attention is given to the matter, and that ordinary diligence in maintenance is observed, the protection afforded by the levee south of Hanlon Heading is sufficient. When thoroughly revetted down to the scour line, the levee cannot be broken by flood.

Head-Gate Foundation.

The only weak point in the line is the head-gate in the Alamo, or Imperial Canal, at Hanlon Heading; and the weakness there is due to the character of the rock foundation, which is not what it was assumed to be by the builders of the gate.

Some have held that the location of the gate in a rock spur of Pilot Knob was not necessarily of strategic importance, and that such a structure might be built safely and satisfactorily on alluvial soil, on the Mexican side of the line, using wooden caissons as a foundation.

Without going into the reasons for this proposed change of location of the head-works, which are political and, in the opinion of the writer, not based on engineering considerations, it seems almost self-

evident that rock foundation is a vital factor in the construction of a head-gate on the Colorado. This is demonstrated, not only by the failure of the structures lacking such foundations, but by the weakness developed in the foundation of the concrete gate at Hanlon Heading.

The Rockwood gate, constructed of timber in 1905, was built in the alluvial bank of the Colorado River in Mexico, some distance from the channel, to serve the double purpose of first controlling the runaway river, and later becoming the head-gate for the Alamo, or Imperial Canal. The writer is familiar with the design and construction, and all problems connected with that gate, and was on the ground at the very moment when it failed. It is his opinion that it would be difficult to devise, for a structure resting on alluvial soil, a more substantial foundation than was designed for this gate. In other words, the Rockwood gate represents a type of construction as nearly perfect as can be devised, at any reasonable expense, for a structure resting on alluvial silt deposits, and yet it failed.

In building structures, whether of wood or concrete, on alluvial soil, the problem presented to the engineer does not concern strength of material and design to meet the stresses to be put on it, so much as it involves provision to meet the boring action of water in front of and back of the structure, wherever large volumes are dealt with. For several months after it is built, the structure must be watched constantly because of the boring action and the resulting settlement or displacement of filling under and around the wings and curtains. After the settlement of the filling, the structure may be reasonably safe for the head under which it was "cured", but an increase or decrease of the head tends to develop new conditions which may cause damage.

This applies to Imperial Valley generally, but the difficulty is even more pronounced along the banks of the Colorado, where the land has been built up in strata of sand and silt containing more or less decayed vegetable matter, and where the structure is subject to extreme variations of pressure induced by a rapidly fluctuating river.

The Rockwood gate failed, not from the pressure of earth or water it was required to withstand, but from the boring which took place in front of the front curtain. In spite of the extended upper curtain, and the extensive apron built in front of the structure, this boring continued to develop with the increased volume of water put

through the gate, until it had entered under the front end of the structure and lifted it bodily from its anchorage.

This might have been avoided had rock and other material been available in quantities sufficient to prevent this scouring, but the same condition might have developed at any time under either wing of the structure, or from leakage through the silt puddle work when the structure was later suddenly subjected to increased water pressure. This is especially true because, during a recent seismic disturbance, the silt puddle work around most of the secondary structures in the canal system was disturbed.

The concrete gate at Hanlon Heading has been in use since November, 1906. During this time it has served its purpose as a regulator in the Imperial Canal, but with excessive operating costs, due to its design, and, as recently discovered, with considerable danger to the system during high water. The cost of handling drift through the gate has been excessive, and represents the largest operating expense of the river division, outside of the dredging of the canal. The enormous quantity of drift which the river brings into the intake and lodges against the gate has, in the past, blocked the openings to such an extent as to cause temporary water shortage in Imperial Valley.

As a partial solution of the drift problem, a sheer boom was built across the mouth of the intake during the season of 1912, and most of the surface drift has been handled successfully at that point, rather than at the gate itself. The submerged drift continued to give trouble by lodgment in the gate tunnels until a new section of the gate was built during the spring of 1913. The construction of the new gate was such as permitted the free passage of submerged drift. The level of the sill of the Hanlon Gate, as originally constructed, was calculated to pass all the water required for irrigation in Imperial Valley without a diversion weir in the river. The width of the structure was in excess of what was calculated for carrying water in the canal alone, as it was presumed that the gate would play a part in turning the water of the Colorado River back to its old channel. The sill proved to be sufficiently low to allow the desired quantity of water to pass over it into the Imperial Canal until 1912; but, because the average bottom of the river was lower during the low-water period than previously, owing to the new route which the river takes to the Gulf through the Bee River, and because the demands for

water during the low stage of the Colorado River were greater than was calculated, the sill of the gate proved to be too high.

During the summer of 1910 it became necessary to construct a rock weir across the Colorado River, in order to divert sufficient water through the gate to meet the demands. The necessity for the weir arose from the fact that the canal above and below the gate had silted, but since then it has developed that, even with the intake clear to the elevation of the former sill of the gate, sufficient water could not have been diverted at the low stage of the river.

It became evident that a second diverting weir would be necessary, or that the sill of the gate would have to be lowered. A permanent weir in the Colorado River was out of the question. The property of the California Development Company was in the hands of a receiver, and he could not do permanent work of this nature; neither were the funds in his hands sufficient to meet the costs of a permanent weir at this point. A temporary weir, such as was constructed in 1910, would not have served the purpose, on account of the heavy maintenance expense and the danger to the levees and banks on both sides of the river, caused by its presence during high water.

It was decided, therefore, to lower one 25-ft. section on the north end of the concrete gate, and in the new opening the radial gates were replaced with a sliding gate of the Stoney type. After the coffer-dams were in place and the excavation work had commenced, a flow of water developed around the end of the coffer-dam connecting with the original concrete gate, and thence inside the coffer-dam. A careful investigation disclosed the fact that the original gate did not rest on solid rock, but on a very inferior grade of decomposed granite, full of soft seams, all of which were water-bearing. This decomposed material had been scoured from under the floor of the old concrete gate until the piers and more than one-half of the original floor had scarcely any foundation left. Holes bored by the water under the original floor were in some places as deep as 8 ft. below the floor line. It is a marvel that the gate had stood, against a head of water varying in the summer from 13 to 16 ft., on the little remaining foundation, through which there must have been constantly a great quantity of percolation. Had this condition been allowed to remain through one, or perhaps two, additional flood seasons of the Colorado River, the remaining foundation would certainly have been

scoured out, causing the complete failure of the structure. This condition under the north side of the gate was corrected in that portion enclosed within the coffer-dam by a series of concrete curtain-walls running down in front and below the structure to serve as cut-off walls. The foundation was refilled with concrete, and a strongly reinforced concrete floor was laid on top. This section of the structure has since been used exclusively during high water, eliminating the danger of failure to a great extent. The weakest point in the primary line of defense, in the writer's opinion, is still the unused portion of the Hanlon gate. The weakness would be many times greater if the structure was in the alluvial deposits along the river bank in Mexico, where even an inferior grade of rock foundation is not to be had.

Temporary Diversion Weir.

Mention has been made of the temporary rock weir built across the Colorado River in the summer of 1910, and the statement has been made that such a weir would not serve as a permanent structure. H. T. Cory, M. Am. Soc. C. E., states that even the comparatively small quantity of rock dumped from the trestle to form this weir was not undermined, and did not settle, except to a slight extent and in a few places, with the summer floods of 1911 and 1912.

In building the weir, 1 822 cu. yd. of rock were used, at a cost of 60 cents per cu. yd. The total cost of the weir, including this rock, plus the cost of providing a trestle and maintaining it during its life, amounted to $32 350. The greatest head developed by the weir was 3.4 ft. on October 19th, 1910, when the Colorado River discharge was 5 000 sec-ft. The only way that this maximum head was developed and maintained was by constant expenditure of money and labor in obtaining rock and filling in the low places along the weir as they developed. In addition to this maintenance cost on the weir itself, there was the cost of maintaining the rock abutments on both ends of the weir up and down stream. The Arizona abutment was maintained at great expense some time after the weir was removed, in order to prevent cutting into the Arizona shore and injury to the levee constructed by the United States Reclamation Service. All this goes to show that such a weir is not practical, from a maintenance point of view alone.

In March, 1911, the trestle was removed and all maintenance work on the weir itself was stopped. For some time previous to March, 1911, no maintenance work was done because of instructions from the War Department that no more material should be dumped into the Colorado River. The average elevation of the crest of the weir was about 108 in October, 1910, and 105 in February, 1911, showing that as soon as the maintenance work was stopped, the rock began to slip down stream. In January, 1913, further investigation of the weir was made, and the elevation of the crest of the rock was found to be below 94, there being only a few places where the rock could be reached by sounding.

Very little good was effected by the weir in the way of securing sufficient discharge through the concrete gate at the low stage of water, after the summer of 1911. It is true that the piling butts, which remained after the blowing of the trestle, caught and held a great quantity of drift, and developed several sand bars in the location of the old weir, but this obstruction caused only a slight increase in the head at the intake.

Sole dependence for a sufficient water supply for Imperial Valley was placed on the hydraulic dredge *Imperial,* operating below the head-gates, and on the dredge *El Centro,* operating above the head-gate in the intake canal and in the Colorado River channel, controlling sand bar obstructions, etc.

The actual computed yardage of solid material moved by the dredge *Imperial* from the canal below the head-gate in one season's operations is equal to just one-tenth of 1% of the solid matter discharged through Hanlon head-gate in the same interval, but it is also a fact that it was just this one-tenth of 1% of solid matter which had heretofore blocked the canal delivery below the head-gate before the dredge was put in operation.

The major part of the one-tenth of 1% of solid matter removed by the *Imperial* was shingle, ranging from 1-in. rock to ¼-in. gravel, and sand ranging from gravel down to materials which are retained on a No. 10 mesh screen. It was the discovery of this fact that led to the successful operation of the Hanlon Heading, from the time of the entire removal of the rock weir in 1911 up to the present. This grade of material has been removed systematically every year since the dredge has been in operation, thus permitting the bed of

the canal below the head-gate to be maintained at an elevation which gave a sufficiently low water surface in the canal at all times. All other sands and silts not removed by the *Imperial* are carried down the canal in suspension.

The fact that there was deposited below the head-gate, at times when the velocities in the intake exceeded 6 ft. per sec., material of a kind which could not be carried down the canal by the velocities below the head-gate, which are never greater than 4 ft. per sec., led to the discovery of a means by which a hydraulic-fill dam could be placed across the Colorado River at a point directly below the intake, to serve as a means of diverting sufficient water into the Imperial Canal, should the necessity ever again arise. This time did arrive during the summer of 1915, because of the combination of an exceptionally low Colorado River during August and September, and an exceptionally great demand for water in Imperial Valley, due to the large increase in irrigated acreage over the previous years.

A study of the cross-section of the channel of the Colorado at Hanlon Heading, and at the gauging station of the United States Reclamation Service at Yuma (Fig. 2), shows that the Colorado—like other rivers forming deltas—scours and refills its channel bed with the increase and decrease of quantities of water, and that a direct relation exists between the character of the materials forming the bed and the velocities of the water. For example: The river bed is scoured to an elevation of 85 at Yuma, Ariz., by a discharge of 140 800 sec-ft., whereas it is refilled to an elevation of about 110 by a discharge of 3 400 sec-ft. The only reason that the bed does not scour deeper than an elevation of 85, with a discharge of 140 800 sec-ft., is that at that depth the materials constituting the bottom are so heavy that the velocities, registered as 6.8 ft. per sec. for this discharge, will not move them. It follows that, in refilling the bed, the materials are graded as to weight, and deposited in direct relation to the velocities. It also follows that the refill in all cases is in strata of materials decreasing in weight as they approach the elevation corresponding with the lesser velocities.

Though this is by no means a new discovery, the experience with the dredge *Imperial* below the head-gate served to bring out more strikingly the real relations between the weights of materials and

the velocities, and showed a way to make a practical use of this knowledge.

The scour line of the bed of the Colorado at Hanlon Heading is at an elevation of about 84. The ladder of the 10-in. suction dredge *El Centro,* operating in the river and above the concrete heading, was designed so as to make it possible to pump from an elevation of 80 when the surface of the river was 110. The materials in this area below the scour line had withstood the scouring effects of velocities as high as 7 and 8 ft. per sec. Those materials, when brought to the surface and deposited in the water where the velocity had decreased to 2 and 3 ft. per sec., due to falling discharge, were certain to stand in the position placed by the discharge of the dredge, making it

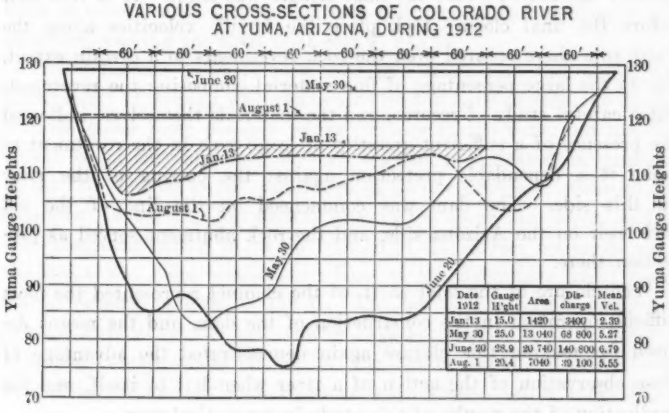

FIG. 2.

possible to construct a hydraulic-fill dam under the water of a running stream varying in depth from 2 to 15 ft.

HYDRAULIC-FILL DIVERSION DAM.

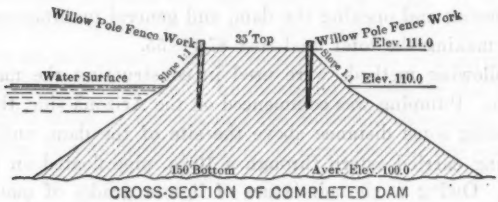
On August 12th, the *El Centro* commenced the construction of such a dam below the intake, and in 14 days had raised the fill to an elevation of 12 in. above the water surface three-fourths the distance across

the river. This fill reached from the Arizona bank of the river to within 250 ft. of the California shore, or a total length of fill of 650 ft. Due to the constriction of the channel during this period, a head of somewhat more than 1 ft. was developed, which resulted in a corresponding increase in velocity through the remaining opening. The velocities resulting from this head became as great as those developed during flood discharge of the river, and consequently material pumped from below the scour line could no longer be deposited in the dam, with any degree of economy, without adopting some method of decreasing the velocities. In closing the last 250 ft., therefore, a great quantity of brush and sacks filled with gravel was used.

The California shore had in years past been thoroughly revetted with a blanket of rock 25 ft. thick, making it safe to drive the channel directly against it, where the final closure was made. It is true that before the final closure took place the terrific velocities along the California shore scoured even the rock revetments to a certain extent, due to the large percentage of fine material composing the revetment, but a careful study of records, and the materials themselves, indicated the presence of a sufficient quantity of large rock in the revetment to make it a dependable protection against the cutting of the river on this side. The dam was commenced on the line of the old rock weir on the Arizona side, and the rock abutment served as protection there.

The closure of the final 75 ft. of the channel represented the most difficult operation in the construction of the dam, and the means devised for making this closure again demonstrated the advantage of close observation of the action of a river when left to itself, and the application of the results of this study in a practical way.

From August 12th to September 12th was the period of principal construction. The time subsequent to September 12th was spent principally in making the final closure and in maintaining the structure. On August 12th the river was discharging 8 800 sec-ft. Of this discharge, 2 529 sec-ft. were flowing into the Imperial Canal, all the gates in the heading being fully opened. The requirement for irrigation in Imperial Valley was 5 000 sec-ft. By September 12th, the river discharge had dropped to 4 000 sec-ft. During this period of 30 days there was used in the construction of the dam:



40 000 cu. yd. of sand and gravel fill, at 2.7 cents per yd.	$1 080.00
21 300 burlap and canvas sacks, at 3 to 6½ cents each	1 140.00
450 cords of willow brush and poles, at 73 cents per cord	328.50
800 lb. of wire	32.00
Cables and clamps	100.00
Labor, filling and placing sacks, carrying and placing brush, poles, etc.	2 000.00
	$4 680.50
Plus 10% for superintendence and tools, etc.	468.05
Total	$5 148.55

Since September 12th there has been an additional expense of $2 000 for raising and strengthening the dam by dredging, and for labor in closing and opening the dam, and general maintenance of the structure, making the total final cost $7 148.55.

The following methods were used in constructing the major part of the dam: Pumping was commenced on the Arizona side, the dredge pontoon being some distance above the site of the dam, and the discharge being carried astern through a 10-in. pipe floated on pontoons to the fill. Owing to the admixture of lighter grades of material encountered in burying the suction pipe to the scour line depth, and to the subsequent caving in on the suction of the surface materials when the depth was once reached, the base of the dam, in a great many places, became as wide as 150 ft. The heaviest materials pumped—in some instances stones and cemented adobe chunks 6 in. in diameter—remained exactly where placed, but the lighter sands and gravel were carried by the current some distance down stream before they lodged in permanent position. When a point near the water surface was reached with the fill, the conservation of the material was made possible by constructing brush fences to help retain the material at the slope required. (Fig. 3.) By this process the structure was carried across the stream to the point of final closure. Three re-runs across were made later with the dredge, bringing the crown to an elevation of 114, which is about 5 ft. above the water surface of the river when 5 000 sec-ft. are passing into the canal. (Figs. 4 and 5.)

On September 10th, 2 300 sec-ft. were passing through the opening in the dam, and 3 300 sec-ft. had been diverted into the Imperial

Canal. The head on the dam was 2 ft., and the resulting velocity through the remaining opening was 8 ft. per sec. The bottom of the opening had been paved with about 10 000 sacks, filled with gravel pumped by the dredge, and stoutly tied, decreasing the depth to about 5 ft., and thereby preventing scour. Great quantities of sacks were used in protecting the Arizona end of the opening, the California shore, as before stated, being protected by its rock facing. Additional sacks were used in forming the overpour riffles as fast as the head developed. A great number of the sacks were of no avail, either because of their lodgment in the wrong place, or because of breaking and washing out; and, throughout the whole process, constant replacements were required because of the boring effects at the toe of the sack riffles, causing the embedding of the sacks.

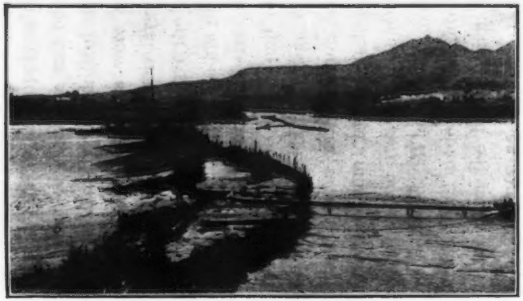
CROSS-SECTION OF COMPLETED DAM

FIG. 3.

In paving the bottom, the point above the opening at which the sacks should be dropped in order that they might lodge on the bottom in the proper place, was determined by constantly experimenting with sacks thrown overboard attached to wires, thus making it possible to locate the sack when it had finally settled by following the line of the wire. Only those filled with the coarsest shingle and gravel and of greatest weight would remain in position and withstand the velocity for any length of time.

In the final closure, when the bottom had been protected carefully, cables were stretched across, securely anchored to deadmen on the California side and in the body of the dam on the Arizona side. The first cables used were of $\frac{3}{4}$-in. plow steel, but proved to be too light when maximum strains were put on them. After one failure in making the closure, due to breaking the cable, a double strand of $1\frac{1}{4}$-in. cable was used for the lower run.

FIG 4.—HYDRAULIC-FILL DAM IN COLORADO RIVER AT HANLON HEADING, FROM ABOVE ON CALIFORNIA SHORE, SEPTEMBER 11TH, 1915.



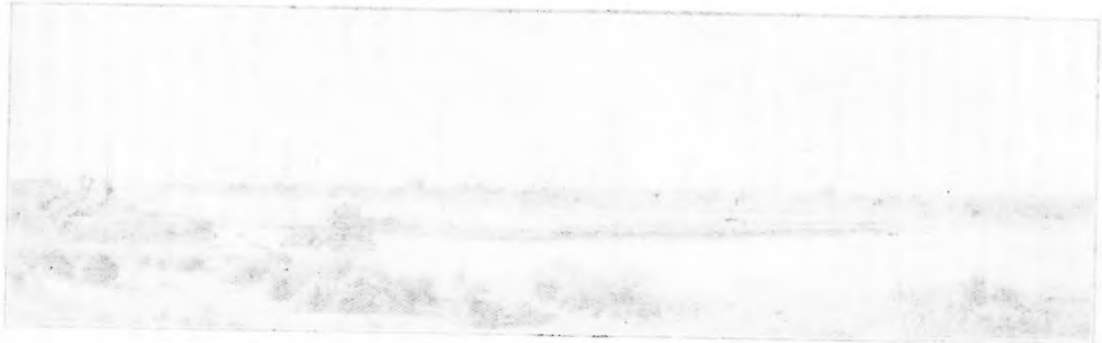


FIG. 5.—HYDRAULIC-FILL DAM, HANLON HEADING, FROM ARIZONA SHORE TOWARD ALAMO INTAKE CANAL, AUGUST 29TH, 1915.

FIG. 6.—CLOSING FINAL OPENING, HYDRAULIC-FILL DAM, HANLON HEADING, SEPTEMBER 11TH, 1915.

Willow poles were cut from the Arizona and California shores near by, where the supply is abundant. The poles were 30 ft. long, the diameter of the large end being 10 in., and the small end tapering to 5 or 6 in. By the skillful use of barges and lines working above the openings, these poles were maneuvered with the current in such a manner as to cause their large ends to lodge against the cable stretched across the opening above the water surface, while the small ends rested on the bottom at an angle of 30°, much as a drifting snag will lodge in a swiftly running stream when the heavy end is dragging the bottom and the upper end encounters a surface obstruction of trees or other large drift. (Figs. 6 and 7.) These poles were placed against the cable, in this manner, with enough space (sometimes 4 or 6 in. between them) to give sufficient strength to the structure and yet not decrease the area in the opening so greatly as to produce much additional head. When all the poles were in place, large bundles of willow brush were made up, weighted heavily with sacks, and rolled into the water from the barges, anchored some distance above the opening, in such manner as to cause them to strike the bottom of the channel and roll against the lower ends of the poles. As additional bundles were thrown in, the pressure against the poles increased, forcing them to bend, until in some instances, before final relief to the strain was obtained, the upper parts of the poles were standing vertically, and the lower sections were bowed to the extreme. Green poles were always chosen because of their flexibility. (Fig. 8.)

The placing of the bundles of brush was carried on in sections only, and only in sufficient quantity to decrease the velocity through the section to a point where material deposited by the dredge could be retained in place. In this manner the strain against the poles in any section of the opening was of short duration, as the dredge would give relief in a few hours by extending the dam above. Of course, a great many sections failed during the work, because of poles breaking, but means were at hand for speedy replacement when such accidents occurred. Because the impounded area above the dam was so great as to require several hours to increase its elevation when flow through the opening was reduced, the extra heads created by stoppage with the brush were not felt on the poles to any great extent before the dredge had given relief.

After numerous local failures, due to small freshet rises in the river, and the breaking of cables and poles, the opening was entirely closed on September 20th, the head then being 6.4 ft. (Figs. 9 and 10), and the discharge of the river, measured at Hanlon Heading, 2 958 sec-ft. Between September 20th and 27th the river discharge fluctuated between 3 000 and 4 000 sec-ft., all of it being required for irrigation in Imperial Valley. On September 27th, because of advance notice from Needles of a rise in the river, the dam was cut at a place provided, and all water, with the exception of 4 000 sec-ft. was passed through into the channel of the Colorado River below. The waters thus let through the dam were forced into the California bank below by local obstructions, so that on October 2d the opening in the dam was again closed, and all the water was diverted into the Imperial Canal. The discharge of the Colorado River on October 2d, as measured at Hanlon Heading, was 4 406 sec-ft. The second closing head was 8.2 ft. (The closing head of the Hind rock-filled dam, on November 4th, 1906, was 15.8 ft., with a river discharge of 9 275 sec-ft.*)

The 36 hours following the second closure were spent in clearing obstructions in the channel immediately below the dam, and in providing a new waterway to train the flow away from the California shore. On the evening of October 3d, the dam was again cut at the place provided, because of a rise in the river in excess of the water requirements in Imperial Valley. During the period from October 3d to the present writing, the opening in the dam, 100 ft. in width, has been left, and through it the discharge has been as great as 8 000 sec-ft. In constructing the dam, provision was made for accommodating the freshet discharges of the river, which commonly occur during October and November. These sections will be sacrificed only as required, because of the fact that during December and January the discharge of the river commonly reaches the minimum, and this being a year of exceptionally low water, it is quite likely that the irrigation requirements of Imperial Valley will again make it necessary to close the dam fully. Entire removal probably will be advisable in March or April, 1916, and by that time it will have fulfilled its purpose as a means of diverting sufficient water to meet the irrigation demands of the Valley. In any event, the annual flow period of May and June,

* "Irrigation and River Control in the Colorado River Delta," by H. T. Cory, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 1204.

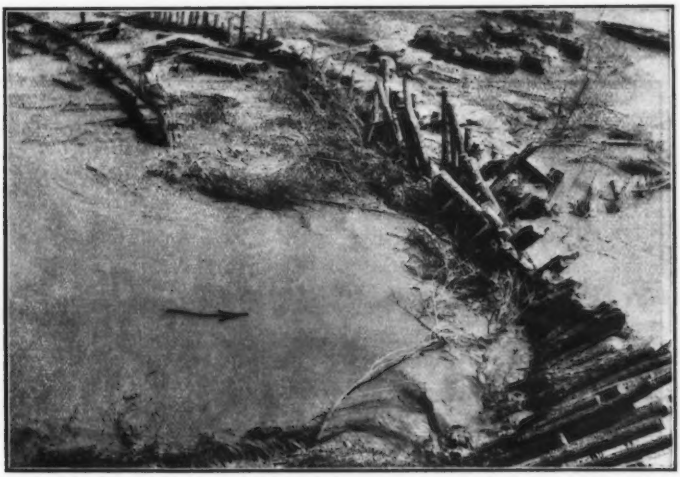

FIG. 8.—REMAINING OPENING IN HYDRAULIC-FILL DAM, HANLON HEADING, SEPTEMBER 17TH, 1915.

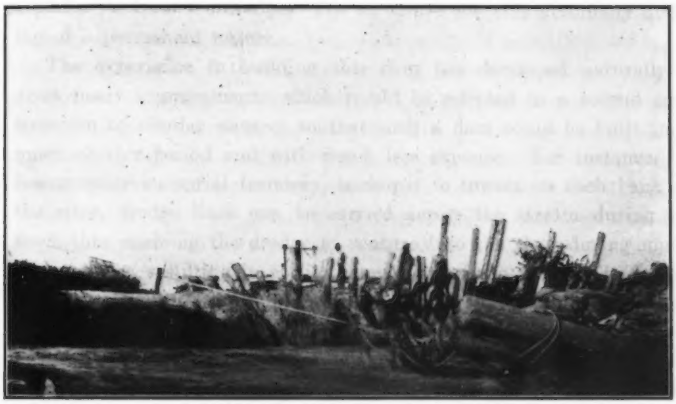

FIG. 9.—FINAL CLOSURE, FROM BELOW HYDRAULIC-FILL DAM, HANLON HEADING, SEPTEMBER 20TH, 1915.

FIG. 10.—DREDGE, *El Centro*, PUMPING IN FINAL CLOSURE, HYDRAULIC-FILL DAM, SEPTEMBER 20TH, 1915.

1916, will remove the structure entirely. If the conditions which develop before this time should require it, the whole structure could be speedily removed by mining, as it is composed entirely of brush, sacks, and gravel, with the exception of a few willow poles driven with the aid of a jet from the dredge. The structure contains absolutely nothing of a permanent nature.

The experience in building this dam has developed naturally a great many improvements which would be adopted in a second construction of similar nature; so that such a dam could be built in a much shorter period and with much less expense. For instance, by constructing an aerial tramway, anchored to towers on each bank of the river, dredge lines can be carried across the stream during its flood, thus enabling the dredge to venture into the river during much higher water, resulting in earlier completion of the work. The ladder of the dredge *El Centro* is to be lengthened 15 ft., enabling it to pump material at a greater depth below the scour line. These two improvements alone will permit the commencement of the dam while the river is discharging 56 000 sec-ft., and will permit the complete diversion of a river carrying 15 000 sec-ft. if necessary. More economical use of sacks and the labor attending can be achieved by a more general use of cable and pole manipulation in closing the final opening. Fewer accidents in the final closure will be assured by anticipating the material requirements in time to accumulate sufficient quantities of poles and brush. By lengthening the pontoon and pipe line of the dredge, thus providing an increased radius of operation, a large supply of material suitable for construction can be obtained.

Closure of Bee River.

The application of a hydraulic-fill diversion dam as the fundamental factor in the closure of the Bee River break in the first line of defense is easily recognized. It is not possible to use the hydraulic fill to close the break itself and to force the river waters back into the old channel of the Colorado, because, in the vicinity of the Bee River break, the Colorado has never maintained a permanent channel bed for any length of time. Each flood, instead of scouring out a well-defined bed and refilling this with material suitable for dam construction, has widened and changed its channel to accommodate the larger volumes of water, deriving its increased sectional area from width, rather than

from depth. Very seldom is the river channel at the end of any flood season in exactly the same location as in the beginning, and for this reason there is no certainty that proper materials for constructing a hydraulic-fill dam at Bee River could be found. On the other hand, in the stretch of river channel from Yuma to a point 4 miles below Hanlon Heading, the river has always, within the memory of man, remained practically in the location it is in to-day, and the successful construction at any place within this radius is assured.

Engineers acquainted with the Colorado Delta agree that the final solution of the problem of control must be the restoration of the river to its old channel. Objections to that plan, which have been raised, are political, and do not apply to the soundness of the plan considered solely from an engineering standpoint. The inexpediency of doing any work of that magnitude in Mexico, until the rights and privileges of citizens of both countries in the matter of use of the river have been readjusted and defined, may be conceded.

There is no longer the imminent menace of disaster to the Imperial Valley canal system that made the closure of the Bee River breach in 1910 apparently an emergency job of vital importance. Construction and adequate maintenance of the line of levees from the old river bank to the west end of Volcano Lake, together with the provision of the interior lines of defense described in this paper, will safeguard the Valley for some time to come.

Therefore, the discussion of methods of closing Bee River and returning the Colorado to its channel close to the Sonora Mesa does not connote advocacy of immediate application of these methods. It is the writer's purpose to show how, in his opinion, such work may be done more readily and cheaply than similar work has been done heretofore, and that the costly processes proposed by some engineers are not essential to successful achievement of the end in view.

Diversion of virtually the entire low-stage flow of the river into the Imperial Valley canals, by the simple and cheap method herein described, removes the first difficulty otherwise to be met in making the closure. It is entirely feasible to make that diversion more nearly complete, and to turn a larger volume of water from the river into the intake and through the gates.

Having taken care of the low-stage flow and dried the river bed at the Bee River break, a levee or earth dam could be constructed

across the break with scrapers, in the same way as levees have been built along the river. It would be advisable, in the writer's opinion, to locate this dam nearer the old channel than the site of the dam with which the Government engineers attempted to close the break in 1910-11. The Government levee, from the C. D. levee down to where it was deflected westward near the break, is in fairly good condition, and should be repaired and utilized. A very important factor in the maintenance of the levee is a railroad on the crest connecting with the track on the C. D. levee. That is the vital factor in all levee protection on the Lower Colorado, a fact now recognized by the United States Reclamation Service engineers, who were unable to maintain the levee of the Yuma Project on the Arizona shore until they followed the example of the C. D. levee and placed on it a track connecting with the rock quarry at Yuma.

It is of primary importance that the Government levee be repaired and the track laid in time to extend it over the Bee River dam as soon as the dam has been completed by the scrapers, in order that rock from the Pilot Knob quarry may be used immediately for the revetment of the levee and dam.

Changes in the location of the dam, and of the connecting levee for short distances from both ends, seem advisable. An important reason for the changes is the resulting reduction of head against the dam and levees during overflow from the old channel.

If the work was to be done as originally projected, doubtless a better location than that of the Government levee could be made, nearer the Sonora Mesa, for the reason that the less room the river is allowed for meandering, the greater its velocity and scouring action, and the easier it is to keep it under control. The advantages, in the case of the Colorado River, of a narrow, confined bed, are to be seen plainly in the stretch of river from Yuma down to a point 4 miles below Hanlon Heading, and, in the writer's opinion, they completely refute the theory that the river should be permitted to meander erratically through the delta. The nearer the river course can be made to an efficient hydraulic channel, the simpler becomes the problem of control.

However, the advantages of a new location may be considered as more than offset by the advantages of the utilization of work already done, one of which is the settling, consolidation, and "seasoning" of

the sections of the Government levee remaining. The original disadvantage of river side borrow-pits has been minimized to a great extent by the growth of brush and willows that has choked them. As time elapses, that obstruction to the flow of water along the foot of the levee increases. It is essential that, in the restoration of the levee south of the break, the river face shall be blanketed with gravel and the track extended to the south end.

The old channel, from the Bee River diversion some 5 or 6 miles southward, would have to be cleared, and it would be advisable to shorten the course by cutting across some of the bends, thereby augmenting the velocity and the scouring action. In opening the old channel, it would be advisable to use a dipper-dredge, making a double cut for about 6 miles. The writer made a reconnaissance of that region recently, and found outside of the old channel a thick jungle of brush, but no big growth and very few trees. The work of clearing off the lines ahead of a dredge would be inconsiderable, as the dredge could handle the brush. In the old river bed, however, the growth of brush and trees has been very rapid and heavy, and it would be necessary to do thorough clearing, and perhaps it would be advisable to break up root growth and loosen the ground with dynamite.

Given a good, clear start down the old channel, the river in flood would cut an adequate course for itself.

Having a track on the levee from Hanlon Heading to the south end, and the quarry at Pilot Knob to furnish unlimited quantities of rock, loaded directly by steam shovel, revetment could be placed readily wherever danger of bank-cutting under the levee might develop. It would not be necessary to revet the entire levee at once. That work should be done as needed, as part of the maintenance, and spread over a long term of years.

Conclusions.

In discussing the control of the Colorado River, as related to the protection of Imperial Valley, most space has been devoted to describing the hydraulic-fill dam, recently constructed across the Colorado at Hanlon Heading, and the possibility of its further use in future river control.

The writer does not mean to state that such a structure could have been used in stopping the breaks of 1905-06, because of the emergency

nature of such work. It is not presumed that such methods can be applied in cases similar to those of the past, where the breaks were stopped while the Colorado River was practically in flood, and where the resulting closing heads were so great as to prohibit the adoption of such means as were used in the recent dam.

Necessity for further emergency work to safeguard Imperial Valley from the flood-waters of the Colorado River no longer exists, and therefore it is possible in the future for the engineer to choose his construction period to conform with the low stages of the river. All the hydrographs of the Colorado River indicate a low period during August, September, December, and January of each year, with very few exceptions, and surely the work can be planned in anticipation of these low stages.

If the engineer will look about him and apply the means at hand in his work, and will study the characteristics of the stream more closely, no such expenditures as have been made in the past will ever again be necessary. The hydraulic-fill dam supplants the trestle and rock-fill dam previously used, which, of course, represents the greatest item of expense in the closure. Not only here is opportunity for great saving of both time and money, but in almost every item of construction is the same opportunity, if the engineer will profit by past experiences and study more closely the examples Nature has provided for him.

DISCUSSION

Mr. Sonderegger.

A. L. SONDEREGGER,* M. AM. SOC. C. E. (by letter).—There are three engineering problems which to-day confront the Imperial Valley Irrigation District and are more or less related to each other: First, the protection from overflow of the Colorado River; second, the silt problem; third, the problem of diverting the low-water flow of the river during the latter part of the summer, when the greater portion, or all, of the flow of the Colorado River is required for irrigation in the valley.

Mr. Allison presents a simple and practicable solution of the first problem. The efficiency of the proposed system of defense can hardly be questioned, as it has already had its practical test, at least in part. The plan includes three main lines of defense.

First line: The diversion of the Colorado River into its old channel along the Arizona and Sonora Mesa; the closure of the breach of the Ockerson levee at the head of the Bee River, together with the restoration of the Ockerson levee, or a new levee similarly situated.

Second line: The westerly portion of the C. D. levee and its prolongation, called the Paredones or Holabird levee, and to the west thereof the Volcano Lake levee.

Third line: The embankment of the Inter-California Railroad as far west as the Alamo-Mocho Canal, and a new proposed levee along this canal and westerly thereof to the West Side Main Canal just south of Calexico.

Of the first line of defense, the upper part of the old C. D. levee, from Hanlon Heading to its junction with the Ockerson levee, has withstood successfully the undermining of the river, wherever riprapped with rock. The break in the levee at "House 7", which occurred in 1914, was due to lack of maintenance. Nevertheless, this first section of levee forms the weakest portion of the whole system of defense.

Mr. Allison has referred to the undermining of the foundations of the old concrete piers built on the granite ledge at the Hanlon head-gate. The writer is quite familiar with these foundations, as the new Stoney gate was put in, during the winter of 1913-14, under his direction as Consulting Engineer for Mr. W. H. Holabird as Receiver. It developed that the granite ledge was a shattered mass of soft rock with many seams of disintegrated granite and strata resembling talcum, sometimes several feet in thickness. There was no need of any blasting, all excavation being made with pick and shovel. The foundations uncovered under the old piers within the temporary coffer-dam were badly undermined. In one instance there

* Los Angeles, Cal.

Mr. Sonderegger.

was a cavity under the down-stream side of a pier large enough to contain an office desk. The 8-in. concrete floor-slab was broken off and eroded in many places. Soundings along the remaining piers showed that they also were badly undermined, although calculations regarding their stability revealed a small margin of safety. Lack of funds prevented the Receiver from repairing the foundations of these piers, and they still constitute a danger which should be eliminated. A granite quarry is within 1 000 ft. of the heading, and, in case of a break, rock could be dumped without delay.

From the heading down to the junction of the Ockerson levee there is only a single line of defense. This section of the levee has already been revetted for some distance. If the levee is watched, no danger need develop, as it carries a standard track, and rock can be dumped at short notice wherever the current approaches the levee. Some of the revetments were lost in January, 1916, owing to absence of maintenance.

Regarding the location of the Ockerson levee, the writer agrees that, as far as river control is concerned, it is of vital importance to concentrate the flow of the river, and to prevent meandering between levees.

As regards the proposed method of closure of the Bee River by a temporary diversion of the Colorado River at Hanlon Heading during the low-water stage, two facts seem to stand out very clearly: first, that the construction of a hydraulic-fill dam can be accomplished successfully; and second, that it can be done at very low expense.

The difficult part of this work—the closure of the last gap in the dam—was effected successfully, not only once, but several times, when it became necessary to cut the dam for the passage of temporary floods; therefore, there can be no doubt as to the success of any future operation of this kind. Both the method and the low cost bear witness to the ingenuity and resourcefulness of the directing engineer.

Considerable dredging will be necessary in the old channel below the Bee River Heading before the river can be diverted permanently. It is probable that the work will extend over a period of 2 or 3 years before a channel can be secured capable of accommodating the winter flow and occasional freshets as they occur; but, unless there are high waters of an extreme nature, and out of season, the writer believes that the diversion can be effected without any great risk.

The second line of defense—the C. D. levee, together with the Holabird and Volcano Lake levees—had proved its efficiency for several years, until in 1914, in the absence of maintenance, a break occurred. The difficulties encountered in the attempt to close the breach indicated clearly the necessity of establishing permanent connection by rail to the Hanlon Quarry. This was done in 1916. This Volcano Lake

Mr. Sonderegger.

levee to-day presents the only protection for the valley. It is partly revetted with rock.

The third line of defense, especially the proposed levee along the Alamo-Mocho Canal, and westward therefrom, also had a partial test during the break in the Volcano Lake levee of 1914. At that time the bank of the Alamo-Mocho Canal intercepted the floods issuing from Volcano Lake, causing them to spread out in a thin sheet over the country to the south and west thereof. This canal crosses the New River channel on a solid embankment, and although it ends about 5 miles to the west thereof, it effectively prevented a concentration of flood waters for several days. The water finally found its way around the end of the canal bank into New River. The levee proposed by Mr. Allison would perfect the existing system of protection.

During the summer of 1916 a new canal was built from the west end of Volcano Lake levee, in a northerly and northwesterly direction, to the intersection of the Wistaria Canal with the West Side Main Canal. This point is about 3½ miles south of Calexico. This canal forms the first side of a triangle, of which the Volcano Lake levee and its extension to the Inter-California Railroad forms the second side, and the railroad levee and the Alamo-Mocho Canal, with its proposed westerly prolongation, the third side. The area over which a flood from Volcano Lake might be spread has been reduced by the construction of this new canal, and a deflection of flood waters to the west is made impossible, unless the new canal is cut. The lowest point of the triangle is at Wistaria Heading. The levee proposed by Mr. Allison, and running from the Alamo-Mocho Canal westward, is still a necessity, in order to close the third side of this triangle and thereby make the third line of defense fully effective.

The question naturally arises as to the effect, on the grade of the river, of the proposed diversion of the Colorado into its old channel: Eventually, it would affect both the levee protection work of the Yuma Project and the diversion into the Alamo Canal of the low-water flow of the river.

From the reports of Col. Ockerson and Mr. Randolph it must be inferred that in 1911 the slope from the head of the Bee River to Volcano Lake was about 2.2 ft. per mile, while along the old channel of the river it was 1.08 ft. per mile. Since 1911 enormous deposits of silt have been carried into the depression of Volcano Lake, so that the grade to the lake has probably decreased. However, there must still be a preponderance of grade in that direction.

It is a fact that the diversion into the lake did cause a recession of grade extending at least as far up as Yuma, and this fact has undoubtedly contributed to the difficulty of diverting the low-water flow into the Alamo Canal. The trouble has become very acute, not only in

Mr. Sonderegger.

the case of extreme low waters, as in 1915 when the river fell to a discharge of 3 000 sec-ft., but also with moderate volumes, as in 1916, when a water shortage occurred in the valley, with a low-water average of 25 000 sec-ft.

It is to be expected that the restoration of the old channel will cause a raising of the river bed, especially at low-water stages. On the other hand, the confining of the flow between the Arizona Mesa and the levee on the west side may cause a concentration of flow at high-water stages, and, simultaneously therewith, a scouring.

Since low waters occur during August, the question of securing a sufficient supply for the valley is second in importance only to the question of defense. It is, furthermore, intimately related to the silt problem, and the two questions will be discussed together.

While in the employ of the Receiver of the California Development Company, the writer, in conjunction with Mr. Allison, made extensive studies regarding the phenomena which affect the diversion of the river at Hanlon Heading.

It should be remembered that the granite ledge which carries Hanlon Heading, is not on the banks of the river, but approximately 2 000 ft. below it. The sills of the old gates are at an elevation of 98 ft., and of the new Stoney gate, at 93; and the low-water stage of the river, of late years, has never fallen below an elevation of 104.3 ft. Theoretically, there has been sufficient fall to effect a diversion, especially since the erection of the Stoney gate in 1914. At the intake of the canal, water is diverted at an angle of 90°, which naturally causes a decrease in velocity from that along the axis of the river. The result is the formation of a bar at the intake.

During high waters this first section of 2 000 ft. of canal above the gate operates as a settling basin. It is about 100 ft. wide, and varies in depth from 3 to 15 ft. With a rising river, the bottom of the canal rises practically at the same time as the water level of the river, causing a silting up of the canal to a depth of 10 ft. or more. Apparently, the cross-section of the canal and the velocity of the water are regulated automatically, corresponding to the volume diverted and the quantity of silt carried by the river. The swift currents carry heavy silt, shingle, and driftwood, large quantities of which are diverted into the canal, having a tendency to pile up in front of the head-gate. Desirable as it might be to prevent the admission of these silt-laden waters, yet the present position of the head-gate makes it necessary to keep its sill clear, so as to prevent the formation of mud banks and log jams immediately above the sill. Once such a bank is formed, it cannot be flushed out, and, with a sudden drop in the river, the heading might be left high and dry. The practice adopted by English engineers with Indian canals—providing gates with two or three leaves,

Mr. Sonderegger.

which enable them, during high water, to skim the water off the top—cannot be adopted for the Alamo heading with the head-gate in its present location.

Immediately below the heading the canal enlarges to a bowl shape with a width of about 200 ft. Here the waters, rushing through the gate, are stilled, and drop their heaviest detritus, the effect being that a bar is formed a few hundred feet below the heading. The width of this bar varies from 1 000 to 2 000 ft. During the high water of 1914, this bar reached an elevation of from 102 to 103 ft.

High waters generally occur in June and July, after which the river drops suddenly. Experience has shown that, if the sill is kept clear, the section of the canal above the gate is scoured practically simultaneously with the drop of the water level of the river, leaving, however, a bar at the entrance. To dispose of this the 10-in. suction dredge *El Centro* is used, and no difficulty has been experienced in keeping the channel open.

Below the gate, however, the bar is not scoured out by a falling river; in such a case, the grade of the intake canal is governed by the water surface in the river, and the elevation of this bar is independent of the elevation of the sills of the gate. In fact, the maximum elevation of the bar has been from 4 to 5 ft. higher than the sills of the old miter gates, and from 9 to 10 ft. higher than the sills of the Stoney gate. The only means of eliminating this bar has been the operation of the 15-in. suction-dredge *Imperial*. In 1914 the bar was reduced to an elevation of 99 ft., sufficient to divert the necessary low-water flow; but in 1915 and 1916 it has required the raising of the water level in the river by temporary dams.

The situation, therefore, is as follows: During high waters large quantities of heavy silt and shingle enter the canal, forming a bar below the head-gate, the elevation of which depends mainly on the high-water conditions of the river. With a drop in the river, its velocities decrease, and the volume of silt carried is reduced correspondingly. The canal then begins to scour in the section above the gate, lowering the bottom automatically. If the drop in the river is not too sudden, this scouring keeps pace with the lowering of the water surface, however, leaving a bar at the intake; but, below the gate, apparently no scouring action occurs, and it requires the operation of a dredge to reduce the lower bar, or the construction of a dam to raise the water level in the river.

In view of these facts, the immediate effect of the restoration of the old channel of the river on the elevation of the low-water level at Hanlon, and the problem of diverting the low-water flow, cannot be predicted with certainty. Undoubtedly, in time, it would be beneficial; but how soon the effect would be noticeable, and whether it

Mr. Sonderegger.

would be sufficient to eliminate the present difficulty completely, are still open questions. In solving the problem, the most important feature is to prevent the heavy silt, which rolls along the river bottom, from entering the canal; especially at high-water stages, only the surface waters of the river should be admitted.

This can be accomplished by constructing head-works along the banks of the river at a point where the current will strike the gate permanently and keep the sill clear.

It is generally admitted that the construction of a permanent dam near Hanlon Heading is excluded, for many obvious reasons. The writer agrees with Mr. Allison that it is not advisable to construct a new heading on the banks of the river on an alluvial silt foundation, even if provided with a rock-fill foundation and extensive rock-fill aprons. This would probably be the method of construction to be adopted if a gate were placed, as has been suggested, at the site of the well-known break of 1906 which was closed by a rock-fill embankment. It is difficult, if not impossible, to estimate the extent of the boring action which will take place in front of a gate during an extreme high water. Undoubtedly, the action is quite different from that occurring along a revetted bank. Provision would have to be made for the maintenance of the rock fill, by a system of tracks commanding the entire up-stream apron and its wings. In order to avoid excessive vibration and a slow wreckage from such forces, an extremely massive concrete floor under the gate proper would have to be provided. At least, a gate in such a location would require unceasing vigil, and present a constant menace to the valley.

However, a location which is worthy of investigation exists on the west bank about 1½ miles above Hanlon Heading, and the writer is informed that this locality is now under consideration by the Imperial Irrigation District.

The bank at that point is on the convex side of the river, and is swept by the main current during the greater part of the year. It consists of a ledge of conglomerate which apparently presents some resistance to the boring and scouring action of the river. It will require careful soundings and investigation before its suitability can be determined definitely.

If the result should be found to be satisfactory, a heading can be constructed in a manner that will prevent heavy silt from entering the canal. The writer believes that even in the absence of special settling basins, the quantity of silt admitted to the canal can be reduced materially, and that this would produce the effect of scouring in the Alamo Canal. The present grade of this canal is practically stationary, and is the result of the discharge of waters carrying extremely high percentages of silt and sand. If operated under the

Mr. Sonderegger.

same grade, but with comparatively clear water, a scouring action is sure to occur. It is a phenomenon often observed in the canals in Imperial Valley.

Probably, as far as the average low-water discharge is concerned, there would be no difficulty in diverting the quantity necessary for irrigation; for extreme low waters, as they have occurred in 1912, 1913, 1914, and 1915, when at times practically the entire flow was diverted, there would still be the necessity for the construction of temporary dams—whether they are hydraulic-fill or rock-fill. It should be remembered that increasing quantities of water will be diverted for the Yuma Project as all its lands are brought under cultivation. Similarly, there is still a constant increase in the acreage in Imperial Valley, so that within a few years the entire low-water flow of the river will be required. This is exemplified in the report* by E. C. LaRue, Assoc. M. Am. Soc. C. E.

It may be stated, therefore, that the reconstruction of the heading on the banks of the river, 1½ miles above Hanlon, even if found practicable, will present but a partial solution of the problem of diverting the low-water flow, and, likewise, only a partial solution as regards the elimination of silt, provided the river maintains its present channel. The successful removal of all silt by settling basins—in the opinion of the writer—depends entirely on the operation of the proposed new heading.

Another plan for securing a sufficient supply of clear water for Imperial Valley is the proposed construction of a canal from Hanlon Heading to Laguna Dam. There will be no engineering difficulties in the construction of the connecting canal. The proposed route crosses several large washes which, at long intervals, are subject to sudden floods resulting from cloudbursts. However, there is sufficient grade available, so that short portions of the canal can be constructed as underground conduits with heavy grades and correspondingly reduced cross-sections; thus, the cost of construction is not likely to be excessive.

There is one feature of this plan which will require careful consideration, namely, the necessity for the continuous operation of the Imperial Canals. The Laguna Project at present diverts probably not in excess of 750 sec-ft. during the summer. In order to have the benefit of the settling basin above the dam, it is necessary to flush the settling pond immediately above the intake one day per week, so that the canals are operated 6 days out of the 7. The distance from Laguna Dam to Yuma is about 12 miles.

It is doubtful whether this mode of operation could be applied to the Imperial system. The summer diversions would be increased from 750 to about 6 000 sec-ft., and, during the low stages of the

* *Water-Supply Paper No. 395.*

river, every drop would be diverted. The distance from Laguna Dam to Imperial Valley is about 75 miles, and, in view of this, it is doubtful whether intermittent operation would be successful. In other words, though the connection with the Laguna Dam would undoubtedly secure a permanent supply, it would not solve the silt problem completely. Mr. Sonderegger.

Whatever solution will finally be chosen, it will necessitate the expenditure of large sums of money, and on the success of the undertaking will depend the future of Imperial Valley. No decision should be made, therefore, except after full and mature consideration of all questions involved.

J. A. OCKERSON,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—In this paper, Mr. Allison presents some very interesting and novel features. His long experience in connection with the irrigation of Imperial Valley gives exceptional weight to his views as to the proper solution of the vexing problems involved. Mr. Ockerson.

Complicated by International Boundary Line.—A comprehensive plan for the reclamation of the Colorado River delta is complicated by the presence of the International Boundary Line between the United States and Mexico.

If that was eliminated, the restoration of the river to its former bed and the limitation of its floods thereto by suitable levees or embankments, together with such revetment as might be necessary to check and prevent excessive bank erosion, would solve the problem of regulation definitely, so far as the river itself is concerned. "Interior lines of defense", which, at best, are temporary makeshifts, would then be unnecessary.

The water of the river, however, is necessary to supply moisture to about 500 000 acres in Imperial Valley, California, and about double that area on the Mexican side of the line. This is more than double the total area of land reclaimed by the United States Reclamation Service, and Imperial Valley alone has a cultivated area measuring more than two-thirds of the total of all the Reclamation projects. This gives a fair measure of the importance of the projects under discussion.

It is the diversion, control, and distribution of this water in Imperial Valley which has largely claimed Mr. Allison's attention for several years, the development of the Mexican side being comparatively small.

The New River Gorge.—The development of the New River gorge is commonly attributed to the break of 1905, when the Colorado River left its channel and emptied its waters into Salton Sea. An investigation of the earliest records left by the stream itself in its wander-

* St. Louis, Mo.

Mr. Ockerson.

ings shows plainly that this diversion to the Salton Sea had occurred many times in the distant past.

Early Mexican maps, dating back to a time before any attempt had been made to divert and control the waters, show the New River gorge to have been developed to a considerable extent even then. The rapid enlargement of the gorge during 1905-06 was most impressive as an example of excavation on a gigantic scale, such as would make the Panama Canal work seem insignificant, and has rarely been equalled elsewhere in Nature.*

Break in the Levee at "House 7".—The author speaks of the breach in the levee at "House 7", and suggests that the use of "jetties" to deflect the current away from the bank would have prevented the damage until rock revetment could have been applied. He also states that there was "no danger of destructive flooding, as the river did not overflow the banks". If the records of the Reclamation Service are correct, the river banks at the point named have never been overflowed by the highest known floods, and why "the simple expedient of building a levee around the break", or why a levee 9 ft. high was ever built at all on a bank which is 4 ft. above the highest known flood, has always been a mystery to the writer. It is fair to say that the author was not responsible for either of these.

Deflecting Dikes or Jetties.—The use of dikes or jetties to deflect the current away from the banks is a common delusion. R. Jasmund, in his review of the regulation of the Rhine, covering some 150 years, recites the "countless failures" in which deflecting dikes had a very large share. He says that, in spite of such dikes inclining down stream, the bank receded more and more and, in many cases, the erosion was strongest just behind the dikes, where protection had been looked for, and the dikes themselves were cut out and disappeared. After being thoroughly tried out, the deflecting type of dike was abandoned, and dikes of suitable length perpendicular to the bank were substituted, which resulted in deposits along the shore below them, which method has had a large part in the successful regulation of the Rhine and other streams.

Like experience on the Mississippi and Missouri Rivers has also demonstrated the futility of current deflectors in the protection of river banks from erosion.

Levees Along the West Bank.—When the break of 1905 was closed, a levee was built to the southward for a few miles, and then turned westward toward the old overflow channel known as the Paredones. It was well known at that time that a break in the near future was imminent by way of Bee River. If, instead of carrying the levee back away from the river, it had been extended down along the river, across and well below the Bee River, which was dry except at flood

* *Transactions*, Am. Soc. C. E., Vol. LIX, Plates V and VI, and p. 37.

stages, the break of 1910 with its attendant losses never would have occurred. It would also have been in line with "final and complete" regulation as advocated by "engineers best acquainted with the problem". Mr. Ockerson.

The writer discussed this matter at the time with those in charge of closing the break, and understood that the plan was to extend the levee down along the west bank of the river to what was reported to be high land well down toward the lower end of the delta. There are, in fact, evidences on the ground, in the nature of a partly constructed levee for a short distance below the point where the levee turns to the westward. It would be interesting to know what caused the change in the plans.

Hydraulic-Fill Dam Across a Flowing River.—The author's success in building, across a flowing river, a hydraulic-fill dam out of material pumped from the lower strata of the bed of the stream is a striking example of what a resourceful engineer can accomplish when an emergency arises.

In his official report of 1910 the writer suggested that the whole operation of the closure of the Bee River break "might be economically handled in the dry", by operating during a low-water season, using the temporary rock-fill dam built just below the intake, and raising it to the required height to divert the whole flow of the river through the Imperial Canal.

The writer's experience does not agree with the statement that the depth of scour is limited by the heavier material composing the bottom, and that "the materials are graded as to weight, and deposited in direct relation to the velocities". In the Mississippi River, the bars composed of gravel larger than the shingle described by the author, extend well above low water, and the deep concave bends opposite the bars have no gravel in them at all. It is not uncommon to see coarse gravel distributed over the high-water banks. Take the exposed section of an alluvial bank in general, all of which has been deposited from a state of suspension, and there is little evidence to show that the materials are graded as to weight.

The scour line of the bed of the river at Yuma is also doubtless influenced by the bed-rock which extends across the river in that vicinity.

The construction of the dam described was only possible during the extremely low stage in the river, amounting to only 4 000 sec-ft., all of which could easily be carried through the head-gates to Imperial Canal. The low cost of the work fully justified the effort, and its novelty and successful outcome reflect great credit on the builder.

It is stated in the press that there is under construction a new temporary rock-fill dam which will cost several times as much as the

Mr. Ockerson.

hydraulic-fill dam under discussion, and it would be interesting to know why the latter was not repeated.

Restoration of Colorado River to Its Former Bed.—The restoration of the Colorado River to its former bed must be realized before a final solution of the problem of control is reached; and, when it is undertaken, the experience gained in the construction of the hydraulic-fill dam can be applied with success. As the author well says, closure should not be attempted under emergency conditions, as heretofore, but a favorable time should be selected, when the whole volume can be diverted down the canal through the head-gates, and then it will be possible to build "dry-shod" such dam or barrier as may be necessary to turn the flow back to its old channel. The latter would also probably need clearing out and rectifying, in order to facilitate the flow.

Railroad on Crown of Levee.—The writer cannot agree that a railroad on the crown of the levee is a "vital factor in all levee protection on the Lower Colorado"; but it may be a convenience in the work of maintenance, which cannot be neglected if the levee is to remain intact.

The writer is of the opinion, also, that, in the use of rock to protect the exposed face of the levee from erosion, economy as well as safety dictates that the rock facing shall be laid by hand with some care, instead of being dumped at random from cars, as a large part of the rock thus dumped serves no useful purpose; witness the levee north of Bee River, which was breached in spite of such protection.

Restricting the River to Narrow Limits.—The author states that "the less room the river is allowed for meandering, the greater its velocity and scouring action, and the easier it is to keep it under control". This statement needs qualification. When the Sonora Mesa is approached, only one bank of the river requires control by revetment; the Mesa itself takes care of the other bank, as do the hills on the right bank from near Yuma to Andrade, which the author cites as a narrow confined bed. Increase of velocity necessarily increases bank erosion, as well as the difficulty of control by bank revetment. Increased velocity does not mean that the energy will all be expended on the bed of the stream, for it will also attack the banks. Therefore, why not give it more lateral room, so as to reduce the flood height?

Location of the Government Levee.—The location of the Government levee on the west bank of the river was fixed after a careful study of the changes in the bank line, as shown on a map defining several positions of the river dating from the earliest surveys.

This study developed the fact that, had a levee been built 20 years earlier, and placed at a distance of 3 000 ft. from the westerly bends of the river, it would have remained intact, as far as river bank erosion was concerned.

Mr. Ockerson.

As the project of 1910 could not cover bank revetment, it was decided to place the Government levee so that it would be safe from destruction by river bank erosion for a probable period of about 20 years, the primary object of the levee being to carry the flood-water so far down stream as to eliminate the possibility of its flowing into Imperial Valley. With the exception of the detour to connect with the Bee River crossing, which was regarded as the best available point, the levee alignment was fixed in accordance with this plan.

In a comprehensive scheme for the regulation of the Colorado River, including bank revetment and flood control, the levee alignment might be somewhat different.

River Side Borrow-Pits.—The author seems to object to river side borrow-pits, which constitute a cardinal principle, followed in all parts of the world, except in the Colorado River delta; and in most of the levees built there that practice has been followed, except when prevented by the encroachment of the water on the river side.

An examination of the Government levee after the floods of 1911 disclosed the fact that there were no channels in the pits paralleling the levee, but, on the contrary, the pits in many cases were obliterated by deposits of sediment. There was no evidence anywhere that the river side pits were responsible for damages to the levee.

The imperative necessity for at least temporary protection of the river slope of the levee was fully realized by the writer, but, when proposed to those "higher up", was rejected, because there was "no authority under the appropriation, or negotiations with Mexico for maintenance".

Hanlon Head-Gates.—Apparently, very little attention had been given to the hydraulics of the river, its variations in stage, and the oscillation in the elevation of the bed conforming in a measure to the stage, until after the concrete head-gates had been placed at Andrade in 1906. Shortly after they were built, it was realized that the sill of the intake, which was 5 ft. below the bed of the river at the time, was too high, and this is what made it necessary to build temporary dams at low stages below the intake, in order to increase the head so as to divert enough water to supply the demands of Imperial Valley.

In July, 1910, the supply dropped to 746 sec-ft., only 395 sec-ft. reaching Imperial Valley. Much of this trouble was due to a silting up of the intake above the head-gates.

Both the United States and Mexico Interested.—A satisfactory and comprehensive solution of conserving, controlling, and using the waters of the Colorado River can only be reached by a joint commission of engineers from both sides of the International boundary line. It has already been too long deferred, and it is hoped that Mexican affairs will before long reach such a peaceful and prosperous state as to permit the consideration of the agricultural and other developments of the delta of the Colorado.

Mr. Allison.

J. C. ALLISON,* ASSOC. M. AM. SOC. C. E. (by letter).—A statement of developments, in the control work of the Colorado River protecting the Imperial Valley, since the paper was written in October, 1915, and since the discussion was published in September, 1916, is of value.

During January, 1916, there occurred the greatest flood ever recorded on the Lower Colorado. At Yuma the discharge was 210 000 sec-ft., or 60 000 sec-ft. in excess of any previous measurement. The restricted channel opposite the Imperial Valley intake carried the flood, without side-scouring and with no meandering of the stream. The channel in the vicinity of "Houses 5 and 6" continued to widen and meander to the extent of undermining the primary line of defense. Bank erosion through the restricted area was not increased in proportion to the stream-bed erosion by the increase in velocity. The writer's statement that "the less room the river is allowed for meandering, the greater its velocity and scouring action, and the easier it is to keep it under control", to which Mr. Ockerson has taken exception, is not only qualified here, but was again proved during the summer flood of 1916. The theory that the greater energy due to increasing velocity is expended on the bed of a stream, and not on the bank, is correct, applied, of course, to locations where the stream alignment is good and where local deflections do not occur. Local deflections will not occur where the stream bed is narrow and deep, but they do occur where it is wide and shallow and the formation of shifting sand-bars is made easily possible.

At the breach in the levees between "Houses 5 and 6", which took place in January, 1916, the Inter-California Railroad, the second line of defense, held the flood-waters, and kept them from entering the Alamo Channel near the site of the original 1906 break. The breach occurred again from lack of maintenance, and the incident does not alter the advisability of retaining this line of defense and the present method of revetment. Where the breach occurred, the levees were designed with land-side borrow-pits, and though the flood-water through the breach entered these land-side borrow-pits, it was easily controlled.

On the Lower Colorado River protective work, past experience demonstrates beyond a doubt that the land-side borrow-pits are more advisable. The writer has even gone so far as to propose in one instance the construction of a drain canal in the borrow-pit parallel with the protective levee, for the purpose of preventing the saturation of the lands adjacent to the levees. In no instance has a levee failure been traced to the presence of a continuous pit on the land side, so long as the width of the levee and the width of the berm are sufficient.

The irrigation system and the system of protective work are now

* Calexico, Cal.

Mr. Allison

in the hands of the Imperial Irrigation District. Improvements to the flood-protection system of the Valley have been begun, the greater part of which are in accordance with the recommendations set forth in the paper. An additional control-gate is now being constructed above the present Hanlon gate, as suggested by Mr. Sonderegger. The abandonment of the southerly end of the Hanlon Head-gate and the construction of additional openings in the rock to the north, are being planned to remedy the defects in that structure, as mentioned in the discussion.

The second line of levee-protection defense has been improved by placing a railroad track thereon throughout the whole extent of the Volcano Lake Levee, in accordance with early suggestions, and it is planned to open a quarry, in addition to the Hanlon Heading quarry, at the Volcano Lake end of the system. It is likewise planned to supply the district with sufficient equipment to facilitate present methods in maintaining the levee, namely, with rock revetment. In this regard, the suggestion made by Mr. Ockerson, which was carried out most efficiently and economically in his reconstruction of the Volcano Lake Levee, namely, that the rock facing should be laid by hand with some care, instead of being dumped at random from cars, is well founded in localities where the levee is not subjected to undermining from the river. This method of revetment is satisfactory for the entire second line of defense for Imperial Valley, but it is not practical on the primary line of defense and its extension, as proposed in the paper, on account of the difficulty of placing such rock to scour-line elevation.

The following is a résumé of the arguments and discussions concerning the theory and practices incident to the construction of a hydraulic-fill dam, as a means of diverting a stream flowing in an alluvial plain, which forms the principal subject of the paper.

The writer has made the statements that: "a direct relation exists between the character of the materials forming the bed and the velocities of the water", that "in refilling the bed, the materials are graded as to weight and deposited in direct relation to the velocities", and that in refilling the bed, the materials decrease "in weight as they approach the elevation corresponding with the lesser velocities." Mr. Ockerson cannot agree with this theory, and cites, as an example, the Mississippi River, in which bars composed of gravel larger than shingle exist well above the lower water, and deep concave bends opposite the bars contain no gravel whatever. Mr. Ockerson's citation is of a stream in which the channel is permitted to deflect from one side to the other, and in which increased areas are developed by side scour rather than by bed scour.

Such a stream as that cited by Mr. Ockerson is that section of the Colorado River at the site of the proposed dam to deflect the Colorado

Mr. Allison.

River water from its present course into the Bee River, back into the old channel of the Colorado. It is on account of such a condition that the writer has proposed the construction of a hydraulic-fill dam up stream some 12 miles, where the channel has been virtually confined to one bed for a great number of years, rather than where it has been shifting in different locations each year. The Mississippi River condition and that which makes possible the construction of the hydraulic-fill dam in the Colorado River at Hanlon Heading and Yuma, are in no wise similar. At Yuma, scour is not influenced by bed-rock, as stated by Mr. Ockerson, because bed-rock at this point is at a considerably lower elevation than the bed-scour line, and a sample of the materials deposited in the bed will reveal that they are graded as to weight, increasing as the scour line is approached.

The construction of a temporary dam in the Colorado River at Hanlon Heading became necessary once more in the summer of 1916. The Irrigation District constructed a rock-fill dam rather than a hydraulic-fill dam, similar to that built the year before, on account of the lack of adequate equipment to permit of the latter type, and because of the greater river discharge at the time the dam became necessary.

The river discharges, throughout the period when the dam was required, exceeded 30 000 sec-ft. The writer is of the opinion that with the proper equipment, as outlined in the discussion of the paper, the hydraulic-fill dam might have been placed successfully, at least with sufficient success to have restricted the channel area and to have developed the necessary head for diversion of sufficient water into the Imperial Valley Canal. As it was, a rock-fill dam was again placed across the Colorado River and later removed, at a total cost of more than $100 000.

Paper No. 1388

TUNNEL WORK ON SECTIONS 8, 9, 10, AND 11, BROADWAY-LEXINGTON AVENUE SUBWAY, NEW YORK CITY*

By Israel V. Werbin, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Maurice Griest, John H. Madden, Robert H. Jacobs, T. Kennard Thomson, John H. Myers, H. G. Moulton, Robert Ridgway, C. V. V. Powers, Francis Donaldson, and Israel V. Werbin.

Synopsis.

This paper describes the work of excavating for and lining the tunnels for the new Lexington Avenue Subway between 53d and 106th Streets, in the Borough of Manhattan, City of New York. Inasmuch as this work involved the driving of tunnels with large and unusual cross-sections, through unsound rock, under busy city streets, and the contract placed on the contractor absolute liability, it has been thought worth while to record the methods used.

The tunnels were built to accommodate two and four tracks, the two-track structure having a cross-section of 32 by 16 ft., the four-track, double-deck structure, 32 by 32 ft., and the four-track structure with all tracks on one level, 60 by 16 ft.

The methods followed in excavating these tunnels through sound and unsound rock and through soft ground are described. In some cases, water was encountered in such quantities as to necessitate the use of compressed-air methods, in order to prevent the loss of materials and the settlement of the local track structure which had

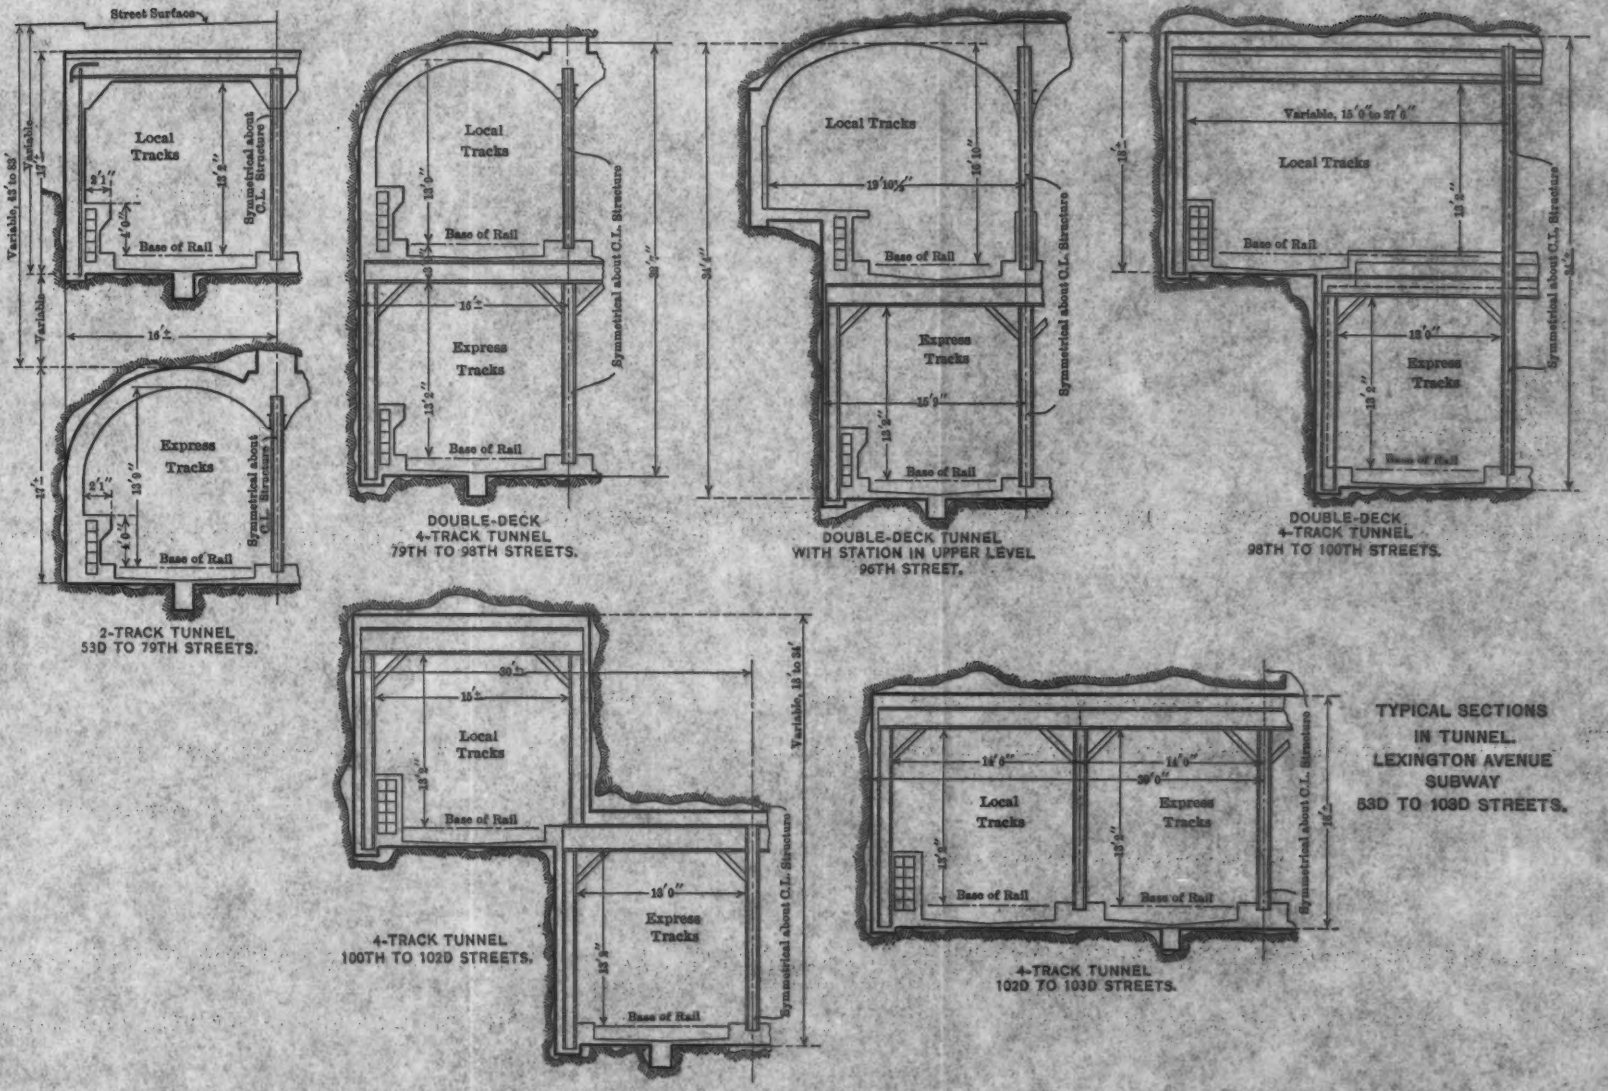
* Presented at the meeting of September 20th, 1916.

previously been completed. The excavation for the four-track structure with the four tracks on the same level had to be made one track at a time, and the manner of making this excavation and protecting the finished part of the structure is described.

Information is also given as to drilling, loading and firing, timbering, plant, cost, etc.

In connection with the lining of the tunnel with concrete, the various types of forms are described; also the manner of handling and placing the concrete.

General.



The Lexington Avenue Subway is being built by the City of New York, under the supervision of the Public Service Commission for the First District of the State of New York, and, when completed, will be operated by the Interborough Rapid Transit Company in accordance with contracts entered into with it by the City of New York acting by the Public Service Commission.

For purposes of organization and construction, the route is divided into sections averaging in length about thirteen or fourteen city blocks.

Section 8 extends from 53d to 67th Street; Section 9 from 67th to 79th Street; Section 10 from 79th to 93d Street; and Section 11 from 93d to 106th Street. The total length of the four sections is 13 992 ft.

The approximate quantity of tunnel excavation made on the four sections was 250 000 cu. yd., and, at the contract prices, the cost of doing this part of the work was approximately $2 250 000. The total cost of all the work on the four sections was approximately $10 500 000, exclusive of track, station finish, and equipment.

The rock encountered in the course of the work on these sections was mostly Manhattan schist of varying degrees of hardness. The greater part of the tunnel being but a comparatively short distance below the street surface, the rock was often blocky, and occasional mud seams were encountered, requiring considerable timbering on Sections 8 and 9. The rock on Sections 10 and 11 was fairly good, and very little timbering was used for this part of the work.

TYPICAL SECTIONS
IN TUNNEL.
LEXINGTON AVENUE
SUBWAY
53D TO 103D STREETS.

General Description of Subway Structure.

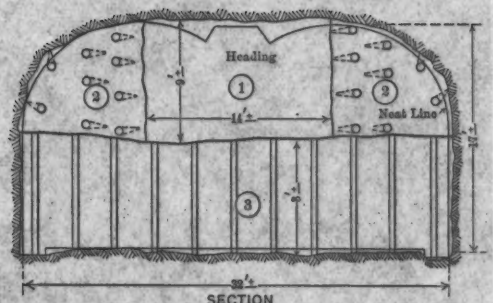
Several different types of subway structure were used on the four sections. On Sections 8 and 9, the local and the express tracks are in separate structures. The local tracks are immediately below the street surface and the work was done by cut-and-cover methods; the express tracks are in separate tunnels below the local tracks. The distance from the street surface to the sub-grade of the express tracks varies from 60 to 100 ft., and the distance between the two levels from 10 to 55 ft., as shown on Plate IV.

The largest part of the structure on Sections 10 and 11 is double-decked, the express being placed immediately below the local tracks. This type prevails from 79th to 99th Street. In the station at 96th Street, the upper level is widened to permit the construction of the station platform (Plate IV). Going north from 99th Street, the local tracks in the upper level diverge until at 100th Street they have been offset sufficiently to clear the express tracks in the lower level. The four tracks then continue northward on approaching grades until at 103d Street they are on the same level, as shown on Plate IV.

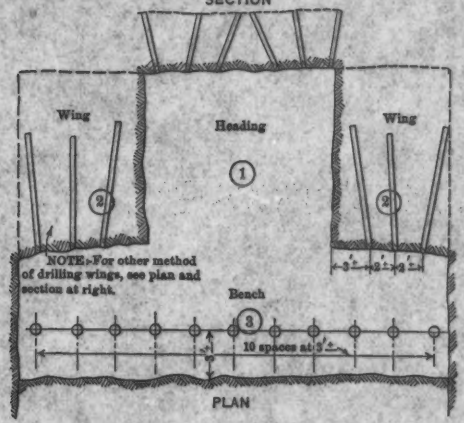
Excavation for Two-Track Tunnel, Sections 8 and 9.

Excavation in Sound Rock.—The excavation for these tunnels through sound rock did not present any exceptional features. The section was taken out with a center top heading and one or two benches, depending on the height of the heading. The center heading was about 9 by 14 ft., the drilling requiring from 24 to 32 holes, depending on the hardness of the rock. Work was carried on continuously for 24 hours per day, with three drilling shifts. The forces were organized so that an advance of about 5 ft. would be made daily. The details of the drilling, loading, and firing are shown on Plate V.

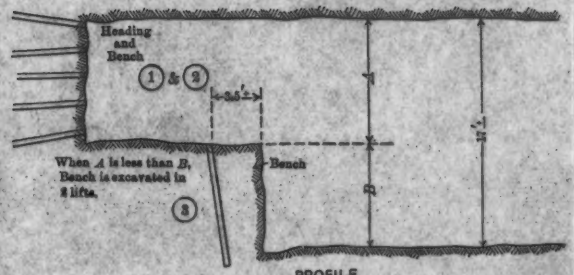
Excavation in Unsound Rock.—In a considerable part of the work, the rock was hard but blocky, and would not permit of making the excavation for the full section without timbering. In most of these cases it was generally possible to excavate enough to permit the erection of the structure for one track without timbering, and after this part had been completed and the rock above had been caught up, the remainder of the section was excavated and the structure completed. (Fig. 1.)



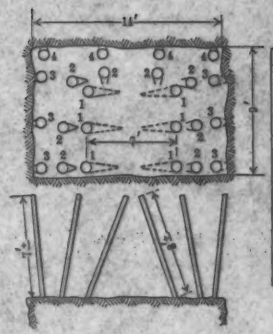
Where the rock was seamy and disintegrated, however, the top side-drift method of tunneling was generally used, segmental timbering being put in, as shown on Plate VI. The side-drifts were generally about 7 by 11 ft. The wall-plates and timbering were set so as to be entirely outside the neat line of the subway structure and there would be no timbers bedded in the concrete lining inside the neat lines. Where soft ground was encountered, poling boards were driven ahead over the sets. The sets were placed about 2 ft. from center to center, 12 by 12-in. yellow pine timbers being used.



In the work on Section 8, where segmental timbering was used, the center pieces of the sets were posted up from the bench, and, as the latter was removed, new posts down to sub-grade were put in, as shown by Fig. 3. In removing the bench, the holes were drilled close together, and light charges of explosives were used in order to minimize the possibility of knocking out the posts. Toward the close of the job, in order to safeguard further this feature of the work, a long, continuous girder was blocked up under the center cap, and this was kept in place until the bench had been removed and new posts, down to sub-grade, had been placed. (Fig. 2.)



On Section 9, after the top heading had been removed, the contractor placed two (and in some cases three) pairs of 24-in. I-beams longitudinally on the bench, and the caps were posted up from these beams. (Fig. 4.) The beams were about 30 ft. long, and were spliced so as to develop their full strength. As the bench was removed, posts were placed under the beams down to the sub-grade. This system of timbering had the advantage that the posts under the caps did not have to be moved in order to make the excavation for the bench. (Fig. 5.)



Often, where the ground was heavy enough to require timbering, water was encountered, and it was desirable to keep this water away from the concrete lining until it had had time to set. Accordingly, the space between and back of the sets was packed with concrete, and later grouted under about 90 lb. pressure. This procedure was effective in keeping out most of the water, and also served to stiffen up the timbering. The final lining was placed tight up against the timber and concrete previously placed, and again grouted if necessary. (Fig. 6.)

METHOD OF EXCAVATION
IN
UNSOUND ROCK
2-TRACK TUNNEL
SECTIONS 8 AND 9

Excavation in Compressed Air.—At 57th and 75th Streets, streams originally crossed Lexington Avenue, and when the excavation was being made for the express tunnels at these places, considerable water was encountered. The contractors had completed the structure for

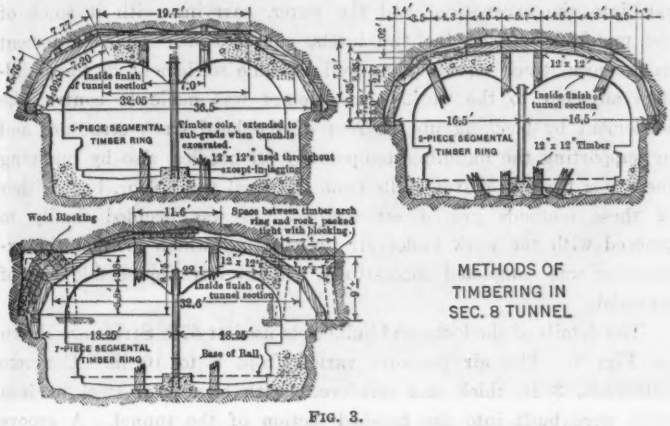

FIG. 3.

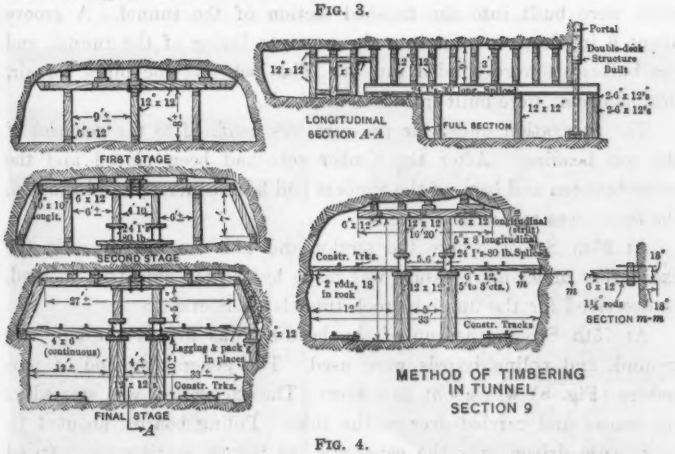

FIG. 4.

the local tracks in the upper level at these points before the work in the express tunnels was undertaken. This had been done in spite of the fact, pointed out to them, that settlement in the local track structure might result if soft ground carrying water was encountered

in the excavation for the express tunnel. As the excavation approached the sites of the old streams at 75th Street, the top of the section ran out of rock, and at 57th Street there were only a few feet of rock cover over the heading. In both places considerable water ran into the excavation, and the water, carrying with it some of the material between the two levels, caused considerable settlement in the local track structure, as well as some settlement in the buildings adjacent to the work. An attempt was made to control the settlement by blocking up the roof of the local track structure and by supporting the buildings temporarily on needles, also by pumping the water through driven wells from the local track floor, but neither of these methods proved satisfactory. It was decided finally to proceed with the work under air pressure, by which method the excavation was completed successfully without any appreciable loss of materials.

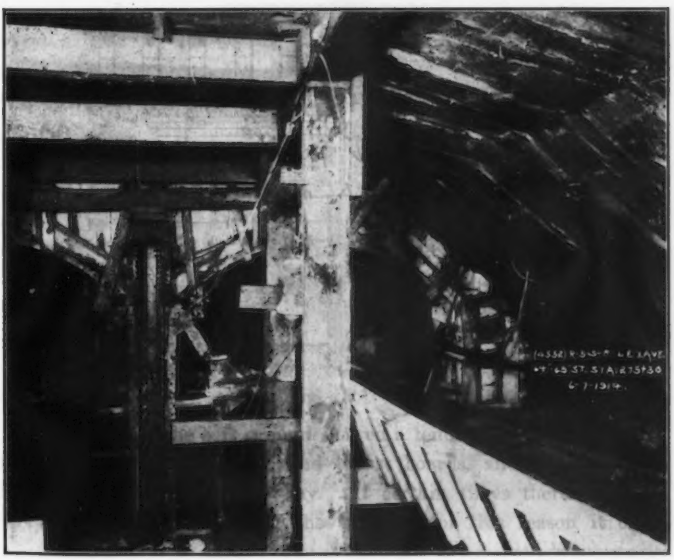
The details of the locks and bulkheads used at 57th Street are shown on Fig. 7. The air pressure varied from 8 to 16 lb. Concrete bulkheads, 3 ft. thick and reinforced with structural steel or iron rails, were built into the finished section of the tunnel. A groove about 6 in. deep was cut into the concrete lining of the tunnel, and the bulkheads were bonded into it. The lock and the pipes for air, drainage, etc., were built into the bulkheads.

The excavation under air pressure was confined to the removal of the top heading. After the timber sets had been placed and the space between and back of the timbers had been concreted and grouted, the bench was removed in free air.

At 57th Street, where the section did not run out of rock, the excavation under air pressure was made by the top side-drift method, as described for the unsound rock tunnels on Section 8.

At 75th Street, the top of the heading was driven through soft ground, and poling boards were used. The general method of procedure (Fig. 8) was about as follows: The excavation was started at the center and carried over to the sides. Poling boards, about 4 ft. long, were driven over the caps, and, as the excavation was carried from the center to the sides, breast boards were placed against the face of the heading and under the ends of the poling boards, until the excavation had been widened enough to permit the placing of another cap, after which the breast boards were removed and the

FIG. 5.—METHOD OF TUNNEL TIMBERING USED ON SECTION 9.



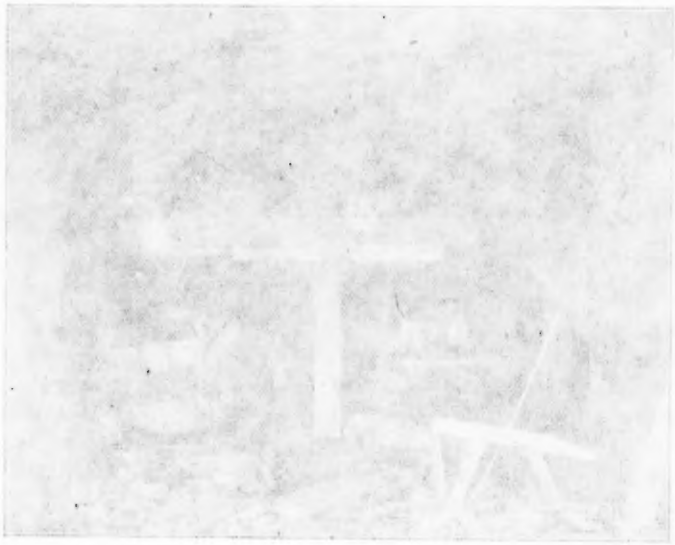


FIG. 6.—SPACE BETWEEN TIMBER SETS CONCRETED.

operation was repeated. After three or four caps had been placed in this way, the excavation was widened out for the wall-plates and side-legs. Where considered necessary, lagging was placed and braced, as shown on Fig. 8.

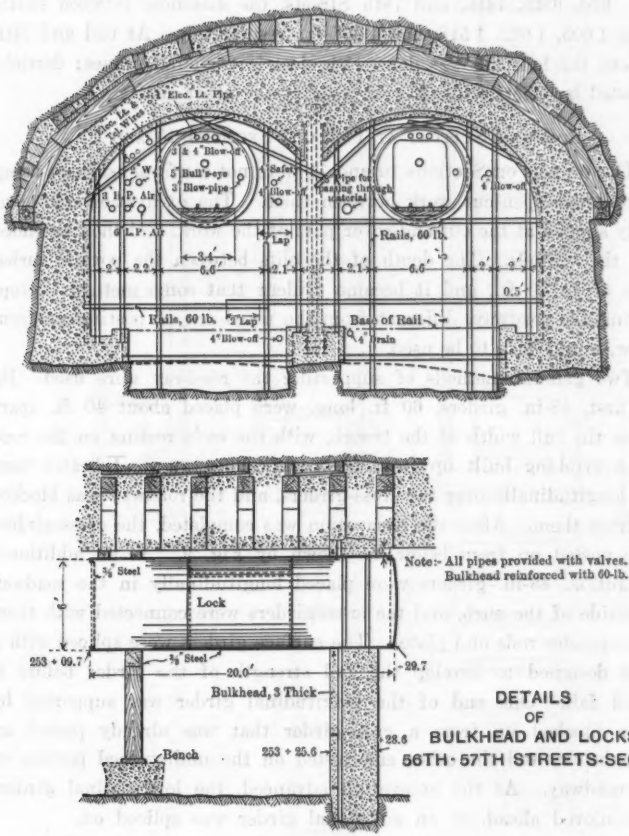

FIG. 7.

In some cases, the soft ground showed a tendency to flow and work its way in between the roof and breast boards, and in such cases the cracks were stuffed with hay. At certain times there was considerable difficulty in holding the air, and for this reason it often

became necessary to caulk the cracks between the timbers with oakum and clay.

Working Shafts.—There were working shafts, for handling the excavated material from the express tunnels on Sections 8 and 9, at 56th, 62d, 68th, 74th, and 78th Streets, the distances between shafts being 1 605, 1 662, 1 518, and 1 057 ft., respectively. At 62d and 74th Streets, the hoisting was done with electric traveling cranes; derricks operated by electric hoists were used at the other shafts.

Roadway Support at Portals, Sections 10 and 11.

The tunnels on Sections 10 and 11 were not continuous, there being stretches of open-cut work between them. The excavation was generally started at the cut-and-cover part of the work, and then extended into the tunnels. The depth of the cuts between the portals varied from 50 to 70 ft., and it became evident that some method of supporting the roadway, different from the usual one of posting up from below, would have to be used.

Two general methods of supporting the roadway were used. By the first, 48-in. girders, 60 ft. long, were placed about 40 ft. apart across the full width of the trench, with the ends resting on the rock or on cribbing built up from the rock. Then 26-in. I-beams were run longitudinally over the cross-girders, and the roadway was blocked up from them. After the excavation was completed, the cross-girders were posted up from below, as shown by Fig. 9. As an additional precaution, 48-in. girders were placed longitudinally in the roadway alongside of the curb, and the cross-girders were connected with them by suspender rods and plates. The surface girders were spliced with a joint designed to develop the full strength of the girder before it would fail. One end of the longitudinal girder was supported by being blocked up from a cross-girder that was already posted up from below, and the other end rested on the undisturbed portion of the roadway. As the excavation advanced, the longitudinal girders were moved ahead, or an additional girder was spliced on.

By the second method, the longitudinal girders just described were used, but 26-in. I-beams running crosswise were suspended from them, and the roadway was blocked up from these cross-beams. The beams were placed about 10 ft. from center to center, and, after the excavation below was completed, the beams were posted up and the longitudinal girders moved ahead. (Fig. 10.)

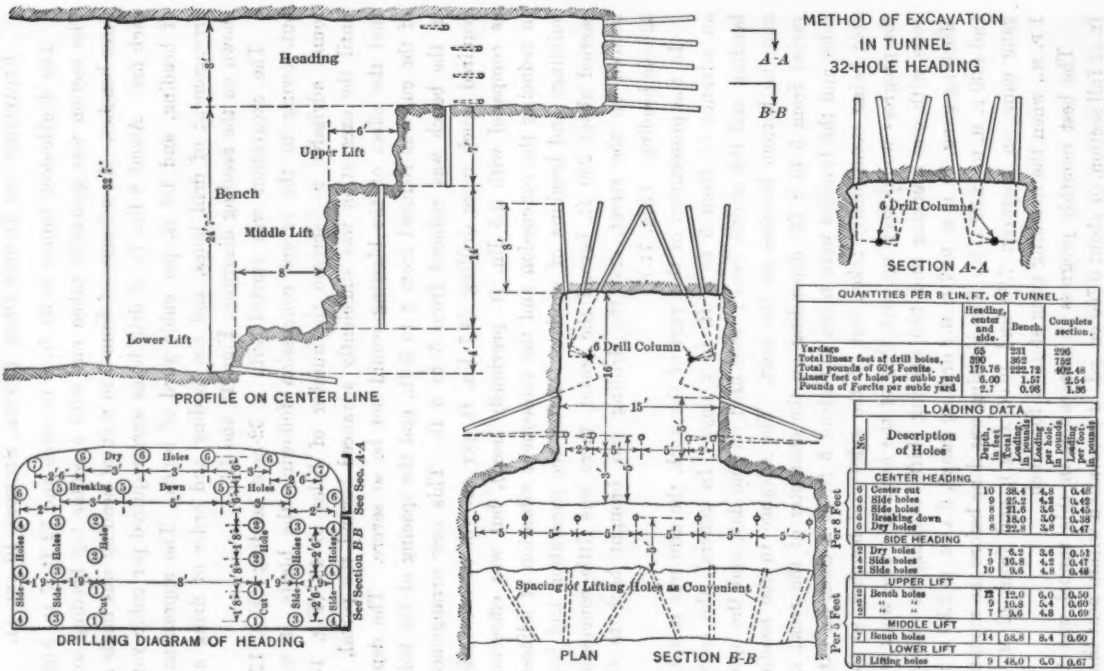
FIG. 9.

FIG. 10.—ROADWAY SUPPORTED ON CROSS-BEAMS, SECTIONS 10 AND 11.

FIG. 11.—EXCAVATION IN DOUBLE-DECK TUNNELS.



EXCAVATION FOR DOUBLE-DECK TUNNEL, SECTIONS 10 AND 11.

The double-deck tunnel is 31 ft. 8 in. wide and 32 ft. 7 in. high. The section was generally taken out with a center top heading and three benches. An advance of from 5 to 8 ft. of heading was made at each fire. About 8 lin. ft. of drill holes were required per cubic yard of heading, and 1.6 ft. per cubic yard of bench. The approximate arrangement of drill holes, and the loading and order of firing are shown on the heading diagrams, Figs. 12 and 13.

The excavation was started with a 32-hole heading (Fig. 12), but, owing to the severe concussion following the blasts, it was found advisable to increase the number of holes to 48 (Fig. 13) until the excavation was sufficiently advanced beyond the portal, so that the effect of the blasting would not be so severe. The depth of the cut was reduced from 8 to 6 ft., and the spacing of the holes in the bench was reduced from 5 to 3 ft. This new arrangement required much more drilling (4.7 lin. ft. per cu. yd. of excavation as compared with 2.5 lin. ft. previously used), but was efficacious in reducing the concussion and the subsequent vibration of adjacent buildings and breaking of windows. After the excavation had been carried about 250 ft. beyond the portal, there was little concussion noticed on the street, and the drilling was brought back to the 32-hole heading. (Fig. 11.)

In the prosecution of this part of the work, the aim was to make an advance of from 5 to 8 ft. in 2 days. In general, the center heading and the middle bench were fired on one day, and the upper and the bottom benches on the next. The advance in the heading varied from 5 to 8 ft., depending on the character of the rock; the sides and the benches were taken out about 5 ft. at a time, an extra shot being occasionally taken out of the sides and benches, so that the progress would keep up with that of the heading. The work was done with one mucking and two drilling shifts working as follows: Mucking gang, 10 A. M. to 7 P. M.; drilling gangs, 6 A. M. to 2.30 P. M., and 4.30 P. M. to 12.30 A. M. The blasting was done before the mucking gang came on (between 7.00 and 10.00 A. M.), and from 12 M. to 1 P. M., when the mucking gang stopped for lunch.

The best monthly progress in excavation in this tunnel was 100 ft. of full section, or about 3 700 cu. yd. of excavation within neat lines.

FIG. 13.

Trimming at Portal and Widening Out for Station Platforms.

Generally, only a few feet of rock cover was found at the portals, and, as this rock was seamy and disintegrated, the excavation was started about 5 ft. below the line of the finished roof and gradually brought up to grade in about 100 ft. At the 95th Street portal, where the work was in the station, no attempt was made at first to excavate for the station platforms, the contractor intending to come back later, after the lower-level structure had been completed, and do this part of the work.

Before the portals were trimmed and the excavation was widened out for the station platforms, the plans were changed so as to substitute steel columns with longitudinal beams or girders on top for the reinforced concrete center wall originally called for. This change of plan greatly simplified the work, and lessened the risk of excavating for the station platforms and trimming at the portals.

As has been noted previously, the rock at the portals was very poor (Fig. 14), and particular care had to be taken not to expose too much of it at a time. The structure for the lower level was first completed (Fig. 16), and also for the upper level inside the portal, where the excavation had already been made to the full section. The work at the center was trimmed carefully to the neat line for about 20 ft., commencing at the point where the upper level had already been completed, and working toward the portal (Fig. 15). While the center was being trimmed, the rock on the sides was made secure by posting or cribbing from the roof of the structure of the lower level. The center line steel and concrete wall was then built for about 15 ft., and carried up solid to the rock above. After the rock was thus caught up at the center, the roof on one side was trimmed and the arch placed (Fig. 17), after which the other side was completed. In this way, by working from the finished structure toward the portal, trimming small stretches at a time, and keeping the exposed rock in the roof well supported, the trimming at the portals and the widening out for the station platforms were accomplished successfully.

Excavation, 99th to 102d Street.

Between 99th and 102d Streets, the transition is made from a double-deck tunnel structure to one with four tracks on the same

FIG. 14.—TYPICAL CONDITION OF ROCK AT THE 95TH AND 96TH STREET PORTALS.

FIG. 15.—CENTER WALL CONSTRUCTION, 96TH STREET STATION.

level. The span of the tunnel at 99th Street is 32 ft. (Fig. 19), and this gradually increases until, at 100th Street, the span is 60 ft. (Plate IV). At this point, the local tracks have been offset sufficiently to clear the two center tracks in the lower level, and continue northward in two separate one-track tunnels, the rock core between them (over the center tracks) not being removed. (Plate IV.)

METHOD OF EXCAVATION
IN TUNNEL
96TH STREET STATION

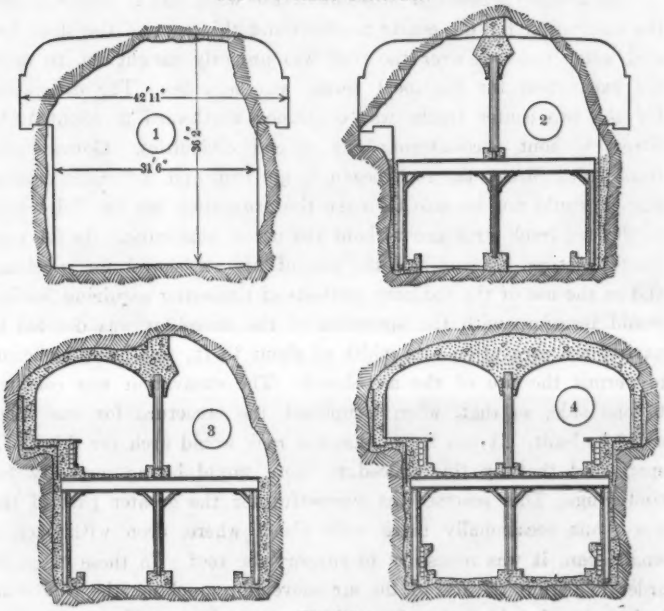

FIG. 16.

In making the excavation for the widening north of 99th Street, a section approximating that of the typical double-deck tunnel was first taken out, and the structure for the lower level completed. The roof was then trimmed at the center to permit the erection of the center steel, and, after the rock was solidly blocked up from the tops of the columns, the excavation was increased to its full width without requiring any additional timbering, except for occasional posting under unsound rock.

The most difficult part of the tunnel work on Lexington Avenue was the excavation for the transition between 100th and 102d Streets. The tunnel for this stretch had a span of 60 ft., and the rock was cut up and disintegrated, and would hardly stand without support for the span of one track (15 ft.). The situation was complicated further by the fact that the plans did not contemplate the excavation of the rock core over the center tracks (lower level) and between the local tracks on the sides.

The general scheme of prosecuting the work was to complete first the excavation for the center tracks, build this part of the structure, and, after the rock over the roof was properly caught up, to make the excavation for the local tracks on the sides. The excavation for the two center tracks was continued northward to about 100th Street without encountering any special difficulties. Going north from 100th Street, the rock began to get bad, and it became evident that it would not be safe to make the excavation for the full width of the two-track structure without the use of timbering. As the contractor desired to continue the use of his air shovel for mucking, and as the use of the ordinary methods of timbering requiring posting would interfere with the operation of the shovel, it was decided to narrow the excavation to a width of about 18 ft., this being sufficient to permit the use of the air shovel. The excavation was confined to one side, so that, when completed, the structure for one track could be built. It was hoped that the rock would arch for this small span, and that by this procedure there would be no necessity for timbering. This scheme was successful for the greater part of the work, but occasionally there were places where, even with such a small span, it was necessary to support the roof. In these cases, in order to permit the use of the air shovel for mucking, the timbering had to be placed so that it would not interfere with the shovel or with the construction that was to follow later.

The general manner of putting in roof supports in these cases (Fig. 21) was about as follows: When unsound rock was encountered, the excavation was advanced with a small heading (8 by 8 ft.), the rock in the heading being secured temporarily by posting. At a point where the excavation to the neat line had been completed previously, recesses were cut in the side rock above the line of the roof of the finished structure, and 24 or 26-in. I-beams were placed

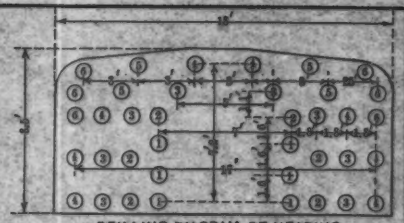
crosswise, with the ends of the beams concreted into these recesses. A temporary horsehead was then set up in the heading, and longitudinal beams were placed, supported on the horsehead and the cross-beams. The rock was then blocked up from the longitudinal beams, and the section was increased to its full width, after which another set of cross-beams was put in just below the horsehead, and the longitudinal beams were brought to bear on this new set. The small heading was then advanced another 50 ft., and the operation repeated.



These systems of timbering were used for about 200 ft. of the tunnel, and though they were efficient for the purpose of supporting the rock and permitting the use of the shovel, they interfered seriously with the progress of the work, as it took about a week to put in about 50 ft. of the timbering, during which period the work of excavation had to be discontinued. For this reason, toward the close of the job, the use of the air shovel was abandoned, the excavation was confined to only one track at a time, and all loose rock was carefully removed. In some cases it became necessary to remove the rock as high as 12 ft. above the roof line, and though the contractor did not receive any payment for the excavation outside of the neat lines, he preferred to remove all loose and dangerous rock rather than attempt to hold it in place with timber. A powerful electric search-light was kept on the job at all times, and examinations of the roof were made several times a week, all loose rock being removed.

The rock throughout this stretch was very poor, and, as very little timbering was used, it was necessary that the excavation be followed by the construction as soon as possible, for, though the roof was carefully scaled, the constant blasting loosened up the rock, so that it was inadvisable to leave it exposed and unsupported for any considerable length of time. Besides, the contractor was not permitted to widen the center excavation for the two tracks until the structure for the one track had been completed and the rock over it had been caught up, or to make the excavation for either local track on the side until the roof of the structure for the adjacent express track had been completed and the rock over it had been safely caught up.

At first, the space over the roof was filled with hand-packed rock, but this proved unsatisfactory, for, when the excavation was made for the local tracks on the sides, the hand-packing was not sufficient to hold the rock core over the express tracks in place. Horizontal

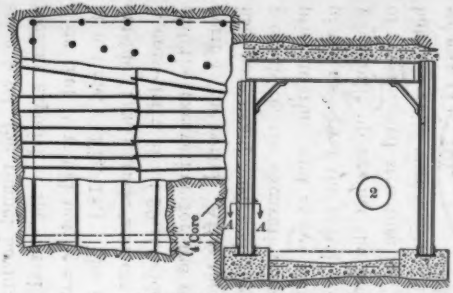
seams started to develop in the core, and the voids in the hand-packing as well as the cracks in the rock core were then grouted with Portland cement grout to prevent bringing concentrated loads on the roof. After this, where the excess space was not too large, or where the rock was very poor, the roof concrete was carried solid to the rock above; where the rock broke very high, continuous longitudinal concrete walls, from 2 to 4 ft. thick, were built over each of the partition walls of the structure and carried solid to the rock above, and the space between the walls was filled with hand-packing (Plate VII).

No attempt was made to excavate for the local tracks on the sides until the adjacent express track structure had been completed and the overlying rock had been caught up. The plans called for an emergency exit to the surface at 100th Street, with a cross-drift over the express tracks connecting the two outside tracks. The contractor used this shaft and drift as working points from which to make the excavation for the local tracks.



While the excavation for the local tracks was being made north and south from 100th Street, work was also started at the 102d Street portal. At this point, the structure consists of four tracks on the same level, the tunnel having a cross-section of 60 by 17 ft. The rock as exposed at the portal was faulted and broken up, and it was clear that it would not be safe to excavate for more than one track at a time. (Fig. 18.) The excavation was first made for the west, outside (local) track, and carried south about 75 ft. from the portal. A cross-drift, about 20 ft. wide, was then carried to the east neat line, and the excavation for the east, outside (local) track was extended north to the portal. After the structure for this part of the excavation had been completed and the roof had been concreted solid to the rock above, the excavation for the two center tracks was made, but prior to this, and as an additional precaution against a movement of the rock over the portal, concrete buttress walls (about 3 ft. thick) were built up against the face of the portal, and rested on the roof of the finished structure in the open cut beyond the portal. Three buttress walls were built, one over each of the partition walls of the subway (Fig. 20).

No special difficulties were encountered in making the excavation for the local tracks on the sides. Precautions, however, had to be taken to protect the adjacent finished structure (Fig. 22).

FIG. 22.

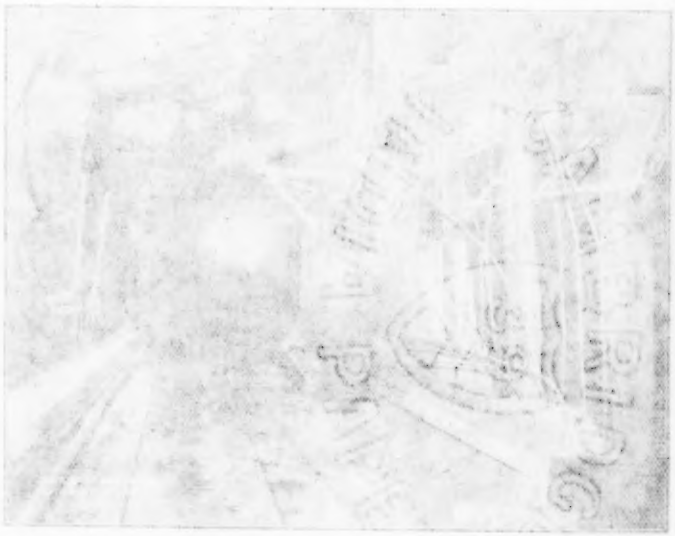

FIG. 23.—EXCAVATION FOR LOCAL TRACKS IN FOUR-TRACK TUNNEL.

FIG. 24.—SUBWAY STRUCTURE DAMAGED BY BLASTING.

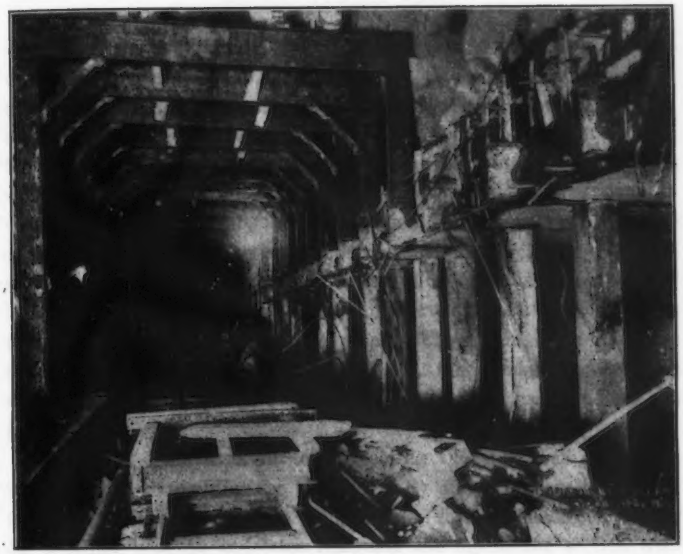

FIG. 25.—DAMAGED COLUMNS REMOVED AND BEAMS SUPPORTED BY 12 BY 12-IN. POSTS.

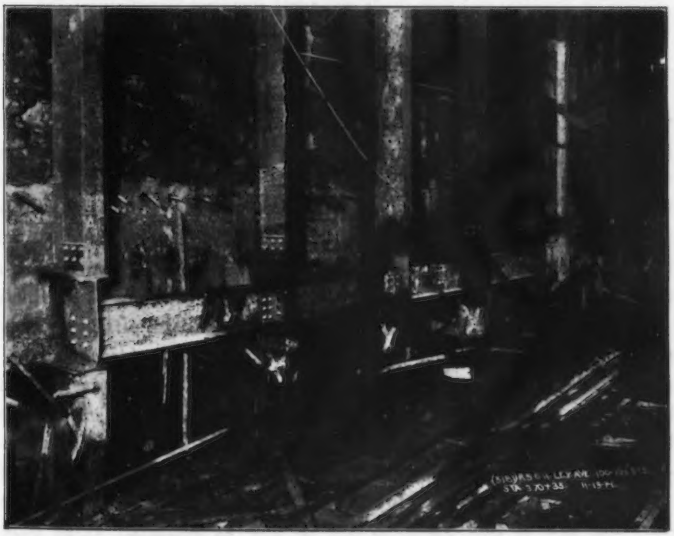

FIG. 26.—BEAM PLACED BETWEEN ROOF BEAMS TO STIFFEN THEM AND DISTRIBUTE THE LOAD ON THE SIDE-WALL.

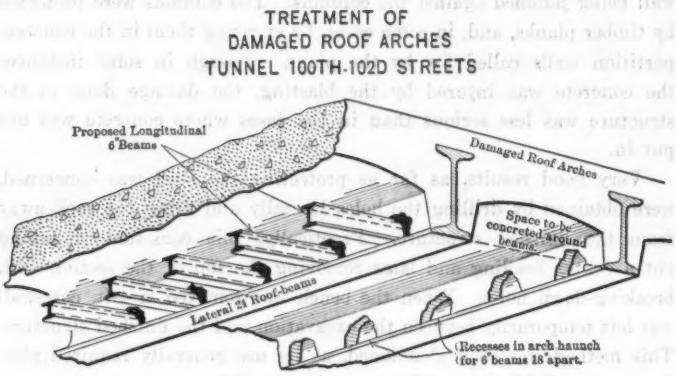

At first, the excavation for each local track was made as a separate tunnel, leaving a core-wall, from 3 to 4 ft. thick, between the excavation and the finished structure. The core-wall was kept about 25 ft. behind the heading, and was shattered so much by the adjacent blasting that it could be easily removed with little drilling and blasting. This method was soon abandoned, as considerable damage was done to the finished structure, by pieces of rock being blown against the columns during the blasting, and also by the rock of the core-wall being jammed against the columns. The columns were protected by timber planks, and, in some cases, by encasing them in the concrete partition walls called for by the plans. Though in some instances the concrete was injured by the blasting, the damage done to the structure was less serious than in the cases where concrete was not put in.

Very good results, as far as protecting the steel was concerned, were obtained by drilling the holes laterally and firing the rock away from the finished structure. Practically, this consisted of taking out a center heading and later removing the top of the section with breaking-down holes. When the bench was removed, a 4-ft. core-wall was left temporarily between the excavation and the finished structure. This method was soon abandoned, as its use generally required platforms or scaffolding on which to set up the drills.

The final and most successful method used was to place a continuous bulkhead of 3-in. planks between the steel and the rock to be excavated, and to brace the columns and partition wall over to the center wall with two 6 by 12-in. braces. The excavation was made with a small top heading and three benches, a 6-ft. core-wall being left temporarily between the bench and the columns. The core was really a part of the bench that had not been drilled, but it was shattered so much by the other blasting that it could be removed later with very little drilling and blasting (Fig. 23).

Considerable damage was done to the structure adjacent to which blasting was done (Fig. 24). The contractor was required to cut out and replace in a satisfactory manner about 200 ft. of 16-in. reinforced concrete wall and columns. Prior to removing the columns, the roof beams were posted up with 12 by 12-in. timbers to prevent any settlement (Fig. 25). In some cases the ends of the center track roof-beams were badly damaged as well as the columns, and it was not con-

sidered safe to attempt to remove them. In these cases a 12-in. I-beam was placed between the roof-beams to stiffen them and to distribute the load over the concrete wall instead of directly on the columns when the side-walls for the local track were placed (Fig. 26). In some cases, also, where jack-arches were used in the roof, they were badly damaged. As it was not considered safe to remove these arches and replace them, 6-in. cross-beams were introduced in the bottom of the arch and grouted, as shown in Fig. 27.

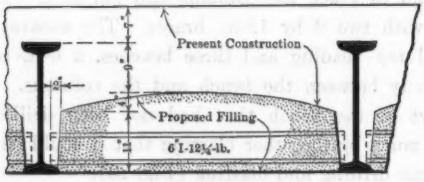

FIG. 27.

Some repair work was also necessary to the local track structures at 56th and 74th Streets, where they had settled on account of the excavation for the express track tunnel. North of 74th Street, considerable voids were found under the track floor. The ground at this point was a soft alluvial soil, and it did not seem likely that any satisfactory results could be obtained by grouting. Accordingly, the

contractor was ordered to re-build the footings under the columns and carry them down to the soil. The track floors were also re-built. South of 74th Street the void space was found under the floor for about 100 ft. of the structure, the voids in some cases being as great as 1 ft. The work in the express tunnel had drained the soil at this point so that it was compact and dry when repairs were to be made. Holes were placed in the local track floor about 10 ft. apart, and the voids were filled with grout. After this was done, investigating holes were again made through the floor and grout, and failed to disclose any void space. At 56th Street, when settlement began to take place, the contractor immediately grouted the space under the local track floor, and this did much toward checking the settlement. Later, when test holes were made through the local track floor, the grout, in some cases, was found to be 20 in. thick, and, as this rested on good soil, it was not necessary to make any material repairs, as it was possible to work up a new grade with the structure in its final location.

Handling of Muck.

In the work on Sections 8 and 9, the mucking was done by hand; on Sections 10 and 11, air shovels were used. The excavated material was loaded into large iron buckets, commonly known on the work as "battleships", and was not handled again until dumped into the scows for disposal. The flat-top trucks used were fitted with cradles to receive the bottom of the "battleships".

Plant.

The contractor's plant was operated by compressed air and electricity. The power-plant for the air was at 96th Street and East River. Electric current was furnished by the New York Edison Company.

Compressed-Air Plant.—The compressed-air plant consisted of five Ingersoll-Rand compressors, each with a capacity of 2 100 cu. ft. of free air per min., and five General Electric synchronous motors, each of 350 h.p., 6 600 volts, and 24.7 amperes. Five receivers were used, two 6 by 18 ft., and three 5 by 15 ft. The air was brought to Lexington Avenue through 96th Street in a 10-in. pipe line. The pipe line was extended north and south of 96th Street to 53d and 106th Streets, and connections were made at the shafts as required. The air was com-

pressed to a pressure of 100 lb., and was delivered in the headings at about 90 lb.

Shovel.—Four 38-ton Marion shovels, Model No. 40, with 1-yd. buckets, were used on Sections 10 and 11. The shovels were provided with 18-ft. booms when working in the double-deck tunnels, but these were cut down to 15 ft. when the shovel was used in the single-deck tunnel.

Hoists.—The electric hoists used at the surface at the shafts were generally Lambert, direct-current, 60-h.p. 230 volts, and 220 amperes. The hoisting engines used below for hauling the mucking cars were Lambert 7 by 10-in. double-drum, and were operated by compressed air.

Electric Searchlight.—The electric searchlight, used in examining the roof of the tunnel before the lining had been placed, was made by the Rushmore Dynamo Works, being described as Type A, 110 volts, and 20 amperes.

Pumps.—In the tunnel, 6-in. Cameron suction pumps, operated by compressed air, were used to discharge the water into sumps, and from there the water was discharged into the sewers by electrically-operated centrifugal pumps.

"Battleships."—The "battleships", or buckets, were made of ¼-in. wrought iron, and were 4 ft. 8 in. by 7 ft. by 3 ft. 10 in. Their capacity was 4.6 cu. yd., water measure.

Drills and Columns.—Ingersoll-Rand 6-in. columns were used to drill the headings. The tripod drills used were generally Ingersoll-Rand, Type E-44 (with 3¼-in. cylinder), F-94 (3⅝-in. cylinder), and E-33 (3¼-in. cylinder). A depth of about 2 ft. was drilled with each sharpening of the steel.

The extensive use of the tripod drills was probably due to the fact that, when this job started, the hammer type then on the market was not very efficient. The maximum length of steel that could be used with such drills at that time was 6 ft. Toward the close of the work, several new kinds of rotary hand-drills were put on the market, and these proved so satisfactory that they practically supplanted the heavier drills formerly used in this work. The first hand-drills used were the McKiernan-Terry non-rotating hand-drill, Style B. These were replaced later by the Ingersoll-Rand rotating hand drills, Type BCR No. 33 and BCR No. 430. The superiority of these small machines over the heavy tripod drills is shown by the fact

that they will drill, on an average, about 30 ft. per hour, and are now supplied with steels up to 12 ft. in length. The saving in labor and power has contributed to the success of these small drills. An ordinary tripod drill with a 3⅝-in. cylinder requires, at 90 lb. pressure, 159 ft. of air, and must have a drill runner and a driller's helper to run it. The BCR No. 33 hand-drill, at the same pressure, requires 90 ft. of air, and can be run by a driller without a helper. The tripod drills require the steel to be changed every 2 ft.; but, with the BCR drill, from 6 to 8 ft. can be drilled without a change.

Drill Steel.—For the large drills, 1¼-in. octagonal steel was used; and for the small drills, ⅞-in. hollow hexagonal steel. A set of steels for the large drills was made up as follows:

Length of steel.	Diameter of steel.
2 ft. 9 in.	3 in.
4 " 0 "	2½ "
6 " 0 "	2¼ "
8 " 0 "	2 "
10 " 0 "	1¾ "
12 " 0 "	1⅝ "
14 " 0 "	1½ "

Cost Data.

The following figures may be considered fairly accurate, as representing the cost of the various classes of work indicated:

Cost of excavation per cubic yard in double-deck tunnels, Sections 10 and 11; sound rock not requiring timbering; mucking done by air shovel..... $5.00

Cost of tunnel excavation per cubic yard in sound rock tunnel, no timbering being used (two-track tunnel, Sections 8 and 9)..... $7.00

Cost of tunnel excavation per cubic yard in unsound rock tunnels, requiring segmental timbering (two-track tunnels, Sections 8 and 9)..... $10.00

Cost of tunnel excavation in compressed air work (10 to 16 lb.). Only top of heading excavated. Segmental timbering used (two-track tunnels, Sections 8 and 9).... $15.00

In computing the foregoing figures, the following scale of wages and general charges were assumed, the scale of wages being based on an 8-hour day:

Superintendent	$300.00	per month.
Tunnel foreman	200.00	" "
Heading foreman	5.00	per day.
Mucking foreman	4.00	" "
Driller	3.68	" "
Driller's helper	2.00	" "
Cranesman	5.00	" "
Shovel runner	6.50	" "
Mucker	2.00	" "
Blacksmith	3.68	" "
Blacksmith's helper	2.00	" "
Electrician	4.80	" "
Electrician's helper	2.20	" "
Drill repairer	3.00	" "
Timekeeper	3.00	" "
Hoist runner	4.75	" "
Signalman	2.00	" "
Three-horse team	9.00	" "
Master mechanic	5.00	" "
Team checker	3.00	" "
Powder	$0.14	per lb.
Dump	0.30	per cu. yd.
Plant running and depreciation	1.42	per cu. yd.*
Administration charges.	10%	of cost of labor and materials.

Concrete Lining.

The plans for the subway structure in the tunnel did not contemplate the placing of the concrete solid to rock in all cases. Where the structure had an arched roof, the side-walls were in all cases to be concreted solid to rock up to 2 ft. above the springing line of the arch. Where the rock was good and did not require any timbering during the progress of the excavation, the regular construction shown

* The figures for the Manhattan tunnels of the Pennsylvania Railroad are given in *Transactions*, Am. Soc. C. E., Vol. LXVIII, p. 192.

FIG. 28.—LONGITUDINAL CONCRETE WALLS OVER ROOF OF TUNNEL.

FIG. 29.—BLAW FORMS USED IN CONCRETING EXPRESS TUNNELS.

on the plans was put in, and a continuous concrete wall, 3 ft. thick, was built over the center wall, solid between the roof and the overlying rock. The space between the top of the side-wall and the center wall was then filled with hand-packing. In the tunnel, with four tracks on the same level, where the steel-bent construction was used, the structure was treated in the same manner, there being a longitudinal wall over each partition wall (Fig. 28).

Where the rock was unsound, and timbering had to be used for support while making the excavation, the structure was generally concreted solid to rock. To strengthen the timbering, the space between and back of the timber sets was first packed with concrete and grouted (Fig. 6), and, later, when the concrete lining was put in, it was placed solid against this concrete and the timber sets and the space between the timbers and the lining grouted. The grout used was generally a 1:1 mixture.

Mixing and Placing Concrete.—Central mixing plants were used on all the four sections. On Sections 8, 10, and 11, the concrete was mixed dry at the mixer, and water was added on the work; on Section 9, just enough water was used to wet the mass, and more was added on the work when considered necessary. The concrete was generally dumped on the roadway decking or on special platforms, and then transferred to the express tunnel below through iron chutes.

Several different methods of handling the concrete in the express tunnels were adopted on different parts of the work. The concrete cars were loaded directly from the chutes from the street surface. At first, the cars were dumped on a platform, and the concrete, after being passed by hand to several working platforms, was deposited in place. This crude method of handling concrete was soon abandoned, and various devices were used so that the concrete could be deposited directly on a working platform from which it could be shoveled into the forms.

On Section 8 (two-track tunnel), the common practice was to use a ramp leading from the floor of the express tunnel to a working platform. The cars were hauled to the platform, and the concrete was dumped and placed in the form by hand. Though this was an advance over the previous method, it was open to the serious objection that the ramps blocked the mucking tracks so that it was impossible to remove any muck while the concreting was being done.

FIG. 33.

Where this objectionable feature became so serious as to interfere materially with the progress of the work, a continuous working platform was built from the chute to that part of the tunnel which was being lined, so that there were separate tracks on different levels for both the mucking and the concrete cars.

To dispense with the necessity of a long working platform and double tracks, the contractor on Section 9 used a lift to raise the concrete cars to the level of the working platform (Fig. 30). The latter was provided with transfer tracks, so that only one lift was necessary to raise the concrete for either arch. This method of

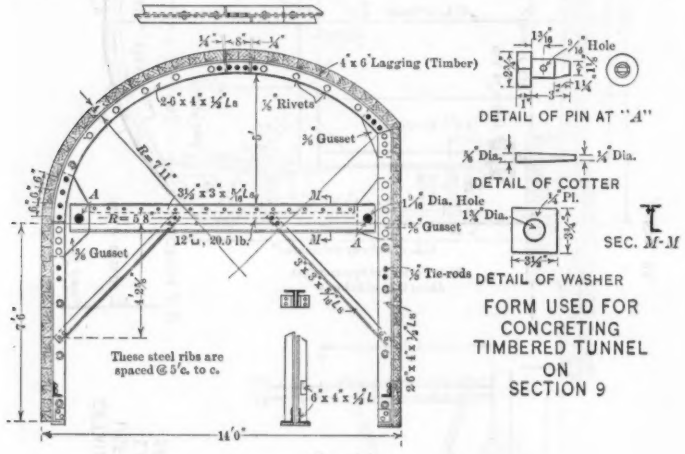

FIG. 34.

handling the concrete eliminated all the objectionable features previously mentioned.

Toward the close of the work, another satisfactory method of handling the concrete in the express levels was introduced on Section 11 (Fig. 31). The concrete car was mounted on a timber framework built on a flatcar, so that the concrete could be dumped directly on the working platform.

A continuous traveler or bucket elevator (Fig. 32) was tried for a short time, but was soon abandoned, as it did not prove very successful. The main objection was that the quantity of concrete that could be handled in this way was too small. The concrete for the

roof was deposited on the platform and then shoveled into the forms; the concrete for the side-walls was dumped in a sloping trough, leading into the forms.

Forms for Concreting.—Figs. 29 to 34 illustrate the principal types of forms used in concreting the express tunnels. Where the excavation was through sound rock which did not require any timbering, the general practice was to use the Blaw movable forms (Figs. 29 and 33). Where the tunnel excavation had to be timbered, the posts prevented the satisfactory use of the Blaw forms, it being impossible to move them. In these cases, forms of wood or those having steel ribs with longitudinal lagging were used (Fig. 34).

The tunnel work was started in April, 1912, and completed in December, 1914. The work was done under the supervision of the Public Service Commission for the First District, Alfred Craven, M. Am. Soc. C. E., Chief Engineer. John H. Madden, Assoc. M. Am. Soc. C. E., was in charge of the construction, as Assistant Division Engineer, until the end of March, 1914, at which time he was assigned to other work. The writer, who had acted as Section Engineer, succeeded Mr. Madden, and continued in charge until the work was completed.

DISCUSSION

Mr. Griest.

MAURICE GRIEST,* ESQ. (by letter).—This paper describes the construction of the rock tunnels in Lexington Avenue from 57th Street to 102d Street. It has been prepared, however, from the point of view of the construction engineer, rather than that of the designer, therefore some special features of the design will be presented, particularly of that portion from 97th Street to 102d Street, where the structure changes from a double-deck tunnel to a four-track tunnel on one level.

Two features seem worthy of brief mention: First, the flat-roof construction with transverse beams and concrete jack-arches and the reasons for its use; and second, the method of reinforcing the structure after the steel therefor was delivered, in order to provide for materially heavier loads than were contemplated originally.

The original design for this portion contemplated the use of concrete arches—twin tubes between 97th and 100th Streets as the local tracks spread out, and four single-track tubes from 100th to 102d Street as the grades approach. In the former case, the clear span varied from 14 to 30 ft.; in the latter case, the spans were uniformly 14 ft. The principal reason for adopting the arch form of construction in preference to the ordinary subway construction, was the greater ease in placing the concrete in the arch form than in the flat roof with smaller clearance above.

It was soon apparent that it would be desirable, on account of the condition of the rock, to construct one track at a time. To do so with the original construction, it would have been necessary to leave the centers in place in one arch until the adjacent arch was poured and packed to rock. Therefore, the ordinary flat roof construction with transverse beams, 5-ft. centers, was substituted, the steelwork being arranged to permit the construction of the center express tracks in advance of the excavation for or construction of the local tracks.

Between 100th and 102d Streets, the roof in general for the ordinary 14-ft. width consisted of a 20-in., 80-lb. beam supported between the tracks by 6-in. plate and angle columns, and at the sides by 12-in., 31½-lb. wall beams, designed for both roof load and side-wall pressure. This roof could carry safely the weight of 12 ft. of rock above it. It was expected that the rock would be sound enough to arch over, so that in no case would there be a weight greater than the foregoing carried by the roof. It was necessary, later, to increase the strength of the roof, for two reasons: first, at 102d Street, on account of the poor rock, open-cut excavation was extended beyond the original portal location, so that the maximum depth of fill over the roof was increased to depths varying from 28 to 38 ft. The roof, therefore, designed to carry 12 ft. of rock, was now to support from 28 to 38 ft. of back-fill.

* Asst. Designing Engr., Public Service Comm., First Dist., New York City.

Mr. Griest.

As described in the paper, the rock in some cases broke out 12 ft. beyond the neat line of excavation, the excess excavation being refilled with hand-packed stone or concrete. In other cases, the rock was poor and seamy, so that the weight to be supported on the roof was problematic. It was necessary, therefore, to make provision for the support of more than 12 ft. of rock for a considerable part of the tunnel.

To meet these conditions, it was necessary to add from 50 to 100% to the strength of the roof. The steel roof-beams were already delivered. Several months would have been required to obtain additional structural steel. The conditions of the rock made it desirable, even imperative, that the permanent construction be placed without delay. The contractor had on hand a supply of rods ordered for other parts of the section. Furthermore, the rock had broken out, as described in the paper, above the neat line of excavation, so that the thickness of the roof could be increased without additional excavation. It was decided, therefore, to omit the jack-arches and increase the thickness of the concrete of the roof, so as to develop in effect a reinforced concrete slab.

The original plans showed an average thickness of concrete 3 in. above the top of the beams. This was increased to 12, 14, and 20 in. in various cases (making the depth of concrete 32, 34, and 40 in., respectively). Four 1-in. tension rods were added in each 5-ft. bay between adjacent bents. Assuming the roof to be a reinforced concrete slab, the reinforcing consisting of the rods and beams, the neutral axis is found to be above the top of the beam. The web of the beam, therefore, assisted in resisting the vertical shear, but did not resist any part of the horizontal shear at the neutral axis. Six ¾-in. inclined shear rods were added, therefore, in each 5-ft. bay over each support. By this method of reinforcing, the supporting power of the roof was increased 50% for 32 in. thickness, 70% for 34 in. thickness, and 110% for 40 in. thickness of concrete.

It was also necessary to reinforce the center walls to carry a load even greater than the supporting power of the roof. (The rock being caught up near or over the center walls and the space filled later with hand-packed stone and rubble, made it probable that a greater loading would be carried on the walls than on the intervening roof beams.) The columns, therefore, were embedded in 12-in. and, in some cases, in 16-in. concrete walls, with eight 1-in. vertical rods in each 5-ft. bay. The load was then assumed to be distributed as in a reinforced concrete wall, over the steel and concrete.

Mr. Madden.

JOHN H. MADDEN,* ASSOC. M. AM. SOC. C. E.—This work was of such magnitude, and the problems presented were so numerous, that the details would readily afford a field for several papers of the extent

* New York City.

Mr. Madden.

of that offered. Under such circumstances, the wisdom of illustrating the text profusely is apparent. The speaker believes that it may be of interest to review the development of the methods adopted for the tunneling operations and the experience during their execution, and, to that end, will devote his remarks in general to the work in progress for the first two years of these contracts, when he was in direct charge of the tunnel construction for the Public Service Commission. The author succeeded to that capacity in April, 1914.

Design.—For subways to carry intraurban traffic it is essential to provide ready access to stations, so as to offer the greatest convenience to the traveling public, and, where the stations occur at frequent intervals, as is necessary in New York City, this demands the minimum depth below the street surface consistent with a feasible re-adjustment of the existing sub-surface structures which will be interfered with. In the work under discussion, this was complicated further by the location of the express stations of the lower level, at which points a practical connection had to be provided with the local or high-level service.

With these considerations in mind, the small rock cover in places, with its incidental construction difficulties in the tunneling, can be readily understood. Future building operations or other sub-surface reconstruction involving a disturbance of existing conditions, was an added factor in the problem of the design of the structure.

Excavation.—The general character of the material encountered in the excavation has been sufficiently described, except that in many places a considerable stratum of destroyed rock, overlying the ledge rock, was penetrated. These deposits had been deprived of their cementing properties, and could usually be removed with a pick and shovel, though, when exposed in the face, they presented every appearance of ledge rock.

On starting the work, there was discussion as to adopting a bottom heading, but, in view of the many faults and seams common to rock of the character of Manhattan schist, it was feared that the use of this method might loosen the overlying material and complicate the subsequent removal of the upper section of the tunnel. With the top heading, support could be provided with the advance, before the ground had an opportunity to work and become heavy.

As shown in the paper, the finished two-track section was about 32 ft. wide, and the roof of the excavation was very flat. To permit the structure to be completed piecemeal, steel columns and longitudinal girders were substituted in the center wall for the original reinforced concrete design. By this means half of the structure could be built and blocked against lateral movement, and thereby avoid exposing the rock for the full section at one time.

Reference is made by the author to the completion of the upper level in advance of the work for the lower tunnels. It must be borne

in mind that it is necessary to maintain progress in work of this character, and that the contractor must base his methods on the preliminary information as to the character of the material which will be encountered. Except where it is known that the tunnel roof will project above the rock outcrop into a sandy soil continuing to the upper level, and thereby induce a bleeding off below that level, with the probable disturbance of the intervening material, extending to either side and entailing settlement outside of the normal limits of the work, it would seem that some advantage can be claimed for this procedure. The completion of the upper level excavation removes the overhead load if poor ground is developed in the tunnel, or if the rock cover above the roof of the tunnel is very thin. The timbering of the upper level excavation may also act to localize any disturbance caused by the tunnel excavation, by retaining the side banks above and diminishing the possibility of an extensive outside settlement. Mr. Madden.

Where apprehension is felt as to settlement from this sequence of operations, it is not believed that underpinning abutting buildings is as effective for their protection against injury as supporting their foundations on cribwork, as the latter admits of correction for settlement and, on the completion of the subway structure, such foundations can be extended to stable ground.

It is not intended, however, to question the wisdom of deferring the construction of the structure at the upper level in advance of the completion of the lower tunnel excavation where the latter is to be conducted through poor material. As stated by the author, where this course was followed, voids were caused under the upper structure, and, in some instances, a cavity was developed between the two levels. An attempt was made to close the neck of this crater with small timber, sealing above it with concrete and packing the sides of the cavity with sand bags to prevent sloughing off. Grout was introduced under pressure from below, in order to consolidate the disturbed ground, but, as no great success was attained in preventing further development of the settlement, it was necessary ultimately to reconstruct the footings and track floor. Indifferent results were likewise obtained from efforts to compact the soft ground underlying the upper level so as to retain it in place during the subsequent excavation from the lower tunnel.

Blasting.—The diagrams and data in the paper supply full details of the blasting operations. Where buildings abut on tunnel work and are founded on the same rock strata to be excavated, some concussion is unavoidable, but the damage from this source was remarkably slight, under the circumstances.

In the vicinity of some of the portals the breakage of windows was quite extensive, because of the air vibrations following the blasting, and though several expedients were tried to break up the velocity of the discharge at the portals, they met with no great success. The

Mr. Madden.

increase in the number of holes or the reduction in the charge of dynamite had no material effect in reducing the damage to the windows. The plate-glass store-fronts were protected with small wooden blocks placed on each side of the glass over which wires were carried to a frame at the top and bottom of the window. This operated to confine the oscillations induced by the vibration, and proved very efficacious in preventing the breaking or cracking of the glass. It was not practical, however, to place this device on each of the great number of small house windows, and, when broken, these were promptly replaced.

Emphasis might well be laid on the use of the powerful searchlight which was mounted on a car in the tunnel and used for periodic inspection of all exposed rock. This readily disclosed any indications of the rock working, or spalls loosening, and suitable precautions could be taken as required. In some instances where the ground was treacherous, the searchlight was used to examine the face of the heading following the blasting and before any men were permitted to enter. Its use was an insurance factor that is worthy of adoption on work of this character.

Timbering.—Where timbering was necessary, the usual segmental type was used, and the design contemplated either the support of the overhead load where the ground was heavy, or protection against injury through the dropping out of spalls or fragments where the rock was firm but blocky. When the soft water-bearing material was encountered at 74th Street, the contractor adopted the expedient (as mentioned by the author) of driving long spikes in the sides of the caps, and these projected from their face and formed a bond; the space between the timber sets was then packed solid with concrete through which the grout pipes extended. This method proved so advantageous that it was used subsequently in other parts of the work to which it would apply.

By this method the timbering was not only greatly reinforced, but a very efficient and uniform support was provided for the roof between the sets. A seal was also obtained for the water draining from above, and, where desirable, this could be collected and removed under control through grout pipes kept open for that purpose. In rock which is seamed and faulted, to the extent of that encountered in many places in this locality, it is important to minimize the time of the exposure of the face in the excavation, so as to reduce the tendency to work; and it is believed that concreting between sets as soon as practical after their erection offers an excellent solution of that problem. This is particularly applicable when the permanent lining cannot be completed coincident with the advance of the tunnel excavation.

As described in the paper, the work presented unusual problems in tunnel construction, and required from the contractors a severe tax on

their experience and resourcefulness. Acknowledgment is due to The Bradley Contracting Company and P. McGovern and Company for the successful completion of their respective sections. Mr. Madden.

ROBERT H. JACOBS,* ASSOC. M. AM. SOC. C. E.—This paper brings forcibly to the mind of the engineer the hazards necessarily incident to execution of work of this character. To those acquainted with such work, it is unnecessary to emphasize the fact that the process of driving tunnels, of the dimensions required for subway operation, in rock such as exists throughout Manhattan, within the limits of city streets, is somewhat hazardous, even when carried on under the strictest and most competent supervision. This applies not only to the force employed, but also to some extent to the public. It is felt, therefore, that it is a matter for congratulation that in the total of 9 700 lin. ft. of tunnel work, including 3 100 lin. ft. of four-track tunnel, covered by this paper, there were no accidents affecting the public, the only injuries suffered being slight damages to buildings due to vibration and concussion, and, in the case of soft ground tunnels, a possible slight settlement in a few buildings. Mr. Jacobs.

Considering the close proximity of buildings (Lexington Avenue being only 75 ft. wide), the character of the material excavated, and the millions of people passing daily over the temporary supports in the case of the cut-and-cover work, the record of casualties for the whole subway work is an enviable one. It may be stated, however, that the various processes of construction cannot be carried on with the same degree of safety as may be obtained in the operation of completed machines or structures. For example, if the same safeguards were thrown around the structural ironworker engaged on the erection of a skyscraper as are thrown around the passenger in the elevator of a completed building, the speaker is sure we would have no skyscrapers. In the same way, if the same safeguards were to be thrown around a tunnel excavator as around a subway passenger, there would be no subways.

It has seemed to the speaker that in undertaking this great work at the behest of our masters, the people, that the latter should be allowed to know in advance that there are certain necessary hazards incidental to such work, no matter how conscientiously and ably planned and executed. He is quite sure that such knowledge would in no wise deter them from their purpose to have these very necessary facilities provided. When, however, the public, through a lack of knowledge of the conditions under which work of this character is carried on, believes that it can and should be carried forward with absolute safety by the exercise of even ordinary care and skill, those in responsible relation to the work are subjected to the most severe criticism or worse, in the case of casualties.

* New York City.

Mr. Jacobs. This is being brought very forcibly to mind at this time by the recent failure of a portion of the erecting appliance of the Quebec Bridge. The general public is quite aware of the fact that the doctor is dealing with certain unknown elements in his work, and therefore does not hold him to strict accountability for the success of his treatment. It does not realize, however, that (although to a very much less extent) there are certain unknown elements which confront the engineer in the prosecution of work, which make it impossible for him to insure that it will be conducted with absolute safety, notwithstanding the fact that he is willing to accept full responsibility for the finished product. The lack of realization of this results in the engineer being held to an accountability which is unfair to the Profession. Here is an opportunity for educational work which can be accomplished by the engineer alone.

Mr. Thomson. T. KENNARD THOMSON,* M. AM. SOC. C. E.—Mr. Werbin is entitled to hearty thanks for his excellent presentation of a very interesting subject.

The speaker cannot help contrasting the difference, in many ways, between the construction of a rock-and-mud tunnel, on which he was engaged 32 years ago, and this up-to-date subway. This is exemplified by the difference between a small tallow candle and a large electric searchlight.

The success of the blasting operations on this work might also be contrasted with a case in New York Harbor some 15 years ago, when a coffer-dam was built as far out as it was considered economical, and the rock excavated inside the coffer-dam in the dry. From the finished excavated space (inside the coffer-dam), some fifty holes were drilled into the rock to be removed, outside the coffer-dam lines.

To ensure success the contractor secured a man from the explosives manufacturer to load the holes and connect the exploders in such a manner as to make a complete circuit. As the current would have to travel through this circuit, it seemed impossible to have a hitch; but only three or four exploders (at different parts of the circuit of fifty) were set off at the first attempt. The wires were then connected again, and a number, but not all, of the remaining charges went off. This naturally put the rest of the work in a very uncertain condition.

In order to ascertain the cause of the failure, the speaker took twenty-five exploders from the same stock, connected them up in the same manner as before, but without the dynamite, threw them into the water, turned on the current, and only four (at intervals) exploded. The remaining twenty-one were again connected up, and all went off together, showing that some of them were just a trifle quicker than the others.

* New York City.

Mr. Thomson.

The author speaks of the considerable quantity of extra rock excavation which the contractor was obliged to do without compensation. This is not equitable, but it seems to be difficult to draw up a contract which will allow for these changes; and, on public work, very few engineers dare to be just, against the terms of the contract and specifications, as they would be accused of graft, etc.

This refusal of the authorities to give the engineers a chance to use their own judgment, however, is costing the country millions of dollars, as the contractors have to bid higher than they would otherwise. As an example, an engineer who, in his time, had a reputation of the very highest, and did an enormous amount of work, got the reputation of refusing to allow any change in his plans and insisting on refinements which did not improve the job. The result was that his clients paid far more for what they got than they would have done otherwise. For instance, the manager of a large manufacturing concern once told the speaker that he always figured work for that engineer just as he would for anybody else and added 25% to the price to cover such arbitrariness.

Mr. Myers.

JOHN H. MYERS,* ASSOC. M. AM. SOC. C. E.—The speaker thinks that engineering literature contains many references to tunnels which approximate the size of the two-track sections described in this paper, and that he is correct when he says that there are few, if any, such references to tunnels similar to the four-track sections. He refers especially to the tunnel of varying cross-section by which is accomplished the transition from double-deck (or two tracks over two) to four tracks abreast between 98th and 102d Streets. He thinks, therefore, that Mr. Werbin has done a valuable service in compiling this accurate and complete record of this work.

There is one theme that runs all through the paper which should be emphasized, and that is the character of the design which permitted what may be termed sectional construction. By this is meant the design which allowed the tunnel lining to follow quickly after the excavation and enabled the constructor to excavate and line part of the tunnel before excavating and lining the remainder. The methods of construction which such a design made possible are illustrated in Figs. 1, 15, 16, 17, 18, 25, and 29, and Plate VII. It is the speaker's opinion that this design aided materially in the successful completion of this very unusual work through a portion of the city which presented many natural difficulties.

The fact that a structure of the magnitude of that described has been built through the heart of the city without material interruption of its mode of living, or of its varied industries, is in itself worthy of note, and the record of the methods used in bringing this about, which the paper provides, is, the speaker believes, of permanent technical and historical value.

* New York City.

Mr. Moulton.

H. G. MOULTON,* ESQ.—The tunnels on Lexington Avenue, especially the double-deck sections, approximately 40 ft. high and 40 ft. wide, are quite unusual in size, from a civil engineering standpoint; yet they are small in comparison with underground excavations required in mining operations. The work on these sections presents problems more nearly comparable to metal mining than those encountered anywhere else on subway construction in New York City.

In mining large bodies of ore, it is often necessary to carry a stope, for a width in excess of 100 ft., to a height of 100 ft. (the usual distance between levels), and for a length of several hundred feet on the strike of the vein, and to carry the walls, roof, and face of the excavation on timbers. As the work on Lexington Avenue is so similar in type, though on a much smaller scale, it is interesting to consider the possibility of adapting to work of this kind the methods used in extracting irregular ore bodies, the dimensions of which are too large to permit the walls and roof to stand for any length of time without support.

There are two marked differences between the excavation methods described in this paper and those which would have been used under metal-mining practice. The first difference is in the method of attack—the use of the top heading instead of a bottom heading, as in mining operations. The second is in the method of timbering the opening—I-beams, segmental sets, etc.

In the very early days of western mining development, it was common practice to remove ore bodies in very much the same manner as that described in this paper. The method is known as underhand stoping, and consists of carrying the upper level of the excavation in advance of the lower, and following in successive levels with the excavation of the bench. As mining methods developed, it was realized that this was the least economical way of attack, and it was abandoned in favor of overhand stoping or, in other words, bottom heading work, in which the lowest part of the excavation is carried well in advance and the back is taken down in successive slices, stepping back consecutively toward the roof. This method has the advantage of less shoveling and also of cheaper breaking, as the rock is broken from an under-cut horizontal face at less cost than from any other position, and also because the drilling can be done with the most efficient types of drills—the so-called stope hammers or buzzers.

In order to hold the walls and roof, and keep the men close to the working face, timbering is placed in sections as the work progresses. The usual dimensions of the timber sets common in metal-mining practice are 7 ft. high, 5 ft. wide between posts, and 5 ft. longitudinally between bents or adjacent rows of posts. The posts, caps, and girts are all framed to exact lengths and provided with horns in daps, so that connection is secured for each member of the set in every direction.

* New York City.

Mr. Moulton.

The rock is broken out in small sections, say, 5 ft. square and 7 ft. high, and another set of timbering is placed. On all slices above the bottom heading, the new post rests directly on top of one of the posts set in the bottom heading, and the cap and girt join with the set at the side and to the rear. In this way the entire mass of rock is removed in a series of inverted steps in such a manner that not more than 5 ft. in either direction is without timber support at any time. The probability of an extensive rock fall is eliminated, and it is possible to work exactly to the pay line of the excavation.

To apply square-set stoping to such an operation as that described in this paper, the first step would be to sink a shaft at one side of the excavation and drive a bottom heading in each direction in the lower corner of the section nearest to the shaft. This bottom heading would be continued through to the next shaft and timbered continuously with the foundation or sill floor timbers of the square-set system. At different places along the heading, the stopes would be started, widened to the opposite side of the section, carried up to the roof, and then continued in both directions until several hundred feet had been opened and timbered. After this, a start would be made on steel erection, the timber sets being pulled out row after row, after alternate bays of steel had been erected and concreted between them. Where no heavy pressures had been developed, the sets would be removed quite readily after knocking out the side and top blocking and wedging. Where heavy pressures had developed from loose ground, it would be necessary to do considerable work with axe and saw on the bottom posts, and ruin part of the timber. Yet, even under the worst circumstances, it is possible that 75% of the timbers could be recovered and used over and over again as the work progressed.

As to the cost of this method, ore is mined on an extensive scale in various districts at costs ranging from $1.50 to $2.50 per ton by square-set stoping at reasonable depths, exclusive of any items corresponding to cost of plant or contractors' profits. This would be equivalent to about $3 to $5 per yd. The timber required would be approximately, 30 ft. b. m. per cu. yd. of material taken out, and, with timber at $60 per ft. b. m. in place, the cost would amount to $1.80 per cu. yd. Considering that most of the timber would be used over and over again, and also that round timbers would be the most advantageous to use, and much less expensive than sawed stuff, it is probable that $1 per cu. yd. would represent the maximum cost for timbering. Against this additional cost there would be certain credits, as compared with carrying the excavation open and with no timbering at all. One such credit would be in cheaper breaking and mucking costs, due to shooting the rock down from an under-cut face and catching it on heaving blocking of poles resting on the caps of the timber sets. It could then be shoveled

Mr. Moulton.

into chutes and drawn into cars in the main bottom heading. Another saving in cost would be realized by working exactly to the pay line, and saving the excess cost of hauling out irregular masses of material, broken away outside of the section, and afterward concreting and backfilling these spaces. In blocky ground, such as was often encountered on Lexington Avenue, it is probable that the credits from the items mentioned would more than offset the additional cost of $1 per cu. yd. for timbering, so that this method might well be cheaper than the ones used.

As to the question of safety, there can be little doubt that full square-set timbering would have the advantage. The great principle involved in keeping rock excavation safe is to have the smallest possible quantity of ground standing without support. On Lexington Avenue, this was done by building the finished structure in sections; but the same thing could have been accomplished, and even greater protection secured, by putting in the timber in small sections and having only the extent of one set open at any one time. Then, the steel structure could be built in its entirety between the timbers at any distance desired behind the face.

As to speed, all the advantages are with the bottom-heading method of attack, as it is possible to open up as many faces as desired dependent only on the hoisting capacity of the shafts.

It is well recognized that even the worst ground may be held with comparative ease before any movement starts, but if once it starts, it may demolish any timbers that can be put in. Close timbering, to prevent the initial slip, may mean all the difference between absolute safety and serious collapse. The wedging and arching action of blocks of rock in unsound ground, together with the frequent resistance on seams, and probably to a certain extent atmospheric pressure, renders valuable assistance to the timbers in holding the ground, and the timber system should provide for this by preventing the initial movement which may destroy all these valuable allies.

As to the timbering methods used in unsound ground on Lexington Avenue, and described in this paper, the speaker is of the opinion that although they served their purpose in giving protection while the work was being carried on, nevertheless, they were unnecessarily expensive and inefficient, as compared with the usual mine-timbering methods. The segmental set, for example, which is used so widely in large tunnel headings, represents the most inefficient and uneconomical manner in which timber can be used. It usually comes down at the joints long before the timber can develop its strength as an arch, and wherever heavy ground is encountered in the roof, the segmental sets must be reinforced with longitudinal horseheads under the top cap and radial posts at the joints. About all that segmental sets will accomplish is the

prevention of spalling and light rock falls from the roof. Where really heavy ground is encountered, as in extracting ore by the caving system, very different methods of timbering are used. Good examples of this are to be seen in some of the leading mines in Arizona, where the ore is extracted by honeycombing the lower part of a block with tunnels and then shooting out the adjacent supporting pillars, so that the entire block drops 6 or 7 ft. and is crushed by its own weight. To keep the main haulage drifts open below such a block of ground, they are timbered with long flat caps reinforced with a short cap in the center, blocked against knee-braces resting on short posts within the main posts of the set. This type of set is so much superior to any attempts to obtain arching action through segmental timbers that it is surprising it is not generally adopted in timbering railroad tunnel headings through heavy ground. Mr. Moulton.

There is a general principle involved in timbering rock excavations, namely, that small posts acting in compression form the most economical method of support. Mine timbering should be placed in small units, and the use of timber in beams or in arches should be avoided as far as possible. There is also a great advantage in smaller units, in that they are easily placed and with fewer men.

The use of many of the methods shown in the paper, such as long I-beams, cribbing built up to support long beams and packing above, is reminiscent of descriptions of the early attempts of metal miners to support ground prior to the development of square-set stoping. The largest timber available was often taken into the mine, and great posts were built up by splicing, perhaps to 60 ft. or more in length. Some of the stopes in the old Elkhorn Mine, in Montana, furnish a good example of these massive long stulls and posts. It requires many times the quantity of timber to work in this way that square-set stoping in small units would call for. Furthermore, the work is not as safe, and the labor required in handling these great units is excessive, as compared with that needed to place the smaller timbers. The same argument applies to the use of I-beams in underground work. Had the miners of a generation ago been able to obtain 24-in. and 36-in. I-beams, they would probably have stuck some of the stopes full of them in desperate attempts to span wide openings and carry the roof without posting support, but they would have soon abandoned them as they did their attempts to splice and build up long posts and beams.

The time required with the mining methods described would depend entirely on the number of faces opened. In the Butte District, which is one of the best examples of square-set stoping in mining operations, well in excess of 10 000 cu. yd. of material are removed daily, from depths ranging from 2 000 to 2 800 ft. below the surface, and the daily extraction is varied in strict accordance with the ore requirements of the smelters, by increasing or decreasing the number of men at work on

Mr. Moulton.

the various stoping faces. If such a method were applied on a job like the Lexington Avenue Subway, it would be merely a matter of carrying the bottom headings clear through and attacking at as many places as desired. The work could be speeded up or slowed down by opening more faces and operating more drills, or by shutting down on different faces.

The whole subject, of course, is quite academic at the present time, because the Lexington Avenue Subway is finished and practically ready for operation. The work there was splendidly done, and the completion of the finished structure in its present form, under the difficult conditions encountered, was a feat for which the Bradley Contracting Company and the Engineering Department of the Public Service Commission justly deserve the fullest measure of congratulation and appreciation. Nevertheless, Lexington Avenue was about the only place on the New York subway construction where metal-mining methods might have been applied extensively with advantage, and this paper, therefore, makes pertinent a general discussion as to comparisons of such methods with those which the contractors adopted.

Mr Ridgway.

ROBERT RIDGWAY,* M. AM. SOC. C. E.—It would seem from a question asked during the discussion of this paper that the author has not made plain the practice followed in loading and firing the heading holes. Only those holes were loaded which were to be fired in one shot. This was also the practice in the headings of the City Aqueduct Tunnel of the Catskill Aqueduct, and is far safer than the method formerly used on some works in the vicinity of New York City, which was to load the whole face before firing any of the holes.

The author has referred to the presence of streams crossing the line of Lexington Avenue at 57th Street and at 75th Street, where soft ground was encountered in the tunnel headings. These streams, of course, indicated valleys in the surface of the country before the streets were graded. These and similar streams along the line of the work added greatly to the difficulties of construction. In some cases, the flow of these streams had been taken care of by roughly built stone culverts, but, in other instances, the street grading had been done without making any provision for the flow, and the water was allowed to flow through the rock back-fill, eventually finding its way into the sewers, or the East River. Relative to this matter, attention is called to the value of the topographical map of Manhattan Island, published in 1874 by Gen. Egbert L. Vielé, as an aid to those doing sub-surface work. This map, popularly known as the "Vielé map", shows the old watercourses and swamps quite accurately, and whenever particularly bad ground was encountered in subway work, the reason for it was usually indicated on this map. An engineer engaged on

* New York City.

foundation work in New York City told the speaker that whenever he is called on to make a special investigation and report on such work, he looks at the "Vielé map" to ascertain whether or not there was an old stream or swamp near the foundation in question. Mr. Ridgway.

The problem to be met by the construction engineers in the work described was a most complicated and difficult one, as a reading of the paper shows. The speaker doubts whether a tunnel more difficult to construct has ever been built in a narrow city street than the one between 99th and 102d Streets. That it was completed successfully, without serious accident of any kind, is cause for congratulation, and indicates the care with which it was supervised. The speaker has an intimate knowledge of this work and is glad to testify to the faithful and intelligent direction of it by the Division Engineer in charge, John H. Myers, Assoc. M. Am. Soc. C. E.; the Assistant Division Engineers, John H. Madden and I. V. Werbin, Associate Members, Am. Soc. C. E.; and the Assistant Engineers in charge of the several sections of construction. Under Mr. Madden the work was begun and well advanced. When he was transferred to other work, he was succeeded by Mr. Werbin, who, up to that time, had been Assistant Engineer on one of the four sections. Mr. Werbin is well fitted to describe the work, on account of his close connection with it and the very careful attention which he has given to all its details of construction.

Much credit is also due the Bradley Contracting Company, the Contractor for Sections 8, 10, and 11, and P. McGovern and Company, the Contractor for Section 9.

There was a large excess of excavation outside of the tunnel lines on the sides and top, and, in order to protect the work and prevent loose rock from coming down, the thickness of the concrete was increased and the walls thus strengthened. Some of the contractors expect to receive compensation for this extra concrete, but none has yet been paid.

C. V. V. Powers,* M. Am. Soc. C. E.—Referring to Mr. Ridgway's remarks about the Vielé map: In the course of some investigation at the office of the Bureau of Street Openings, the speaker found original maps and surveys much older than the Vielé map. They are interesting and valuable as giving first-hand information in very considerable detail concerning old surface conditions. Any one desiring to consult them can no doubt do so by making proper application. Much of the information contained in the Vielé map was probably taken and condensed from these earlier drawings. Mr. Powers.

Francis Donaldson,* Esq. (by letter).—The writer has read with interest Mr. Werbin's paper describing the construction of the Lexington Avenue Subway tunnels, and Mr. Moulton's discussion of it. He has also noted Mr. Moulton's conclusion that the work could have Mr. Donaldson.

* New York City.

Mr. Donaldson.

been performed more economically and safely by mining with square-set timbers than by the timbering methods actually used. The writer has driven tunnels with both top and bottom headings, is familiar with mining practice, as well as with the Lexington Avenue work, and yet is unable to agree with Mr. Moulton, whose conclusion is too sweeping, to say the least.

In the first place, the choice of a method in any kind of construction must be governed by the results desired. In ore mining, the requirement is the excavation of the maximum quantity of material at the lowest cost consistent with safety, whereas, in driving a tunnel beneath a New York City street, it is not so important to excavate material at the lowest cost per ton hoisted as to excavate it in such a way as to prevent the settlement of the surrounding ground and facilitate the construction of the permanent lining. Secondly, the successful application of any method depends largely on local conditions, and a plan that might be best in California, where timber is cheap and intelligent miners plentiful, might not work at all in New York City.

To build the subway tunnels from 53d to 106th Street was a big job, and it had to be done in a limited time. It was necessary to adopt methods which would enable the kind of labor available in the vicinity to be used to advantage. New York City was full of good tunnel men of all kinds, from superintendents to muckers, who had learned their business on the many aqueduct and subway tunnels recently driven in and around the city and in near-by States, but there were few miners, in the western sense. If mining methods had been required by the contract, it would have been a practical impossibility to build up an organization of miners large enough to complete the work in the required time. That tunneling methods were proper, when viewed from this standpoint, is shown by the fact that the job was completed on time and in a satisfactory manner.

To consider more specifically the different types of tunnel structures described in the paper: The express tracks in Sections 8 and 9, between 53d and 79th Streets, were in a tunnel very nearly equivalent to a standard double-track railway tunnel, driven for the most part in solid rock, and lined with a concrete arch. It is generally believed by American tunnel engineers—certainly by the writer—that the top heading and bench method is the cheapest and best for tunnels of this type, and that, where timbering is necessary, segmental timber fills the bill.

Examples of the successful use of segmental timbering in tunnels through all kinds of ground are so frequent that it is hardly worth while to refer to them; but one recent instance refutes Mr. Moulton's condemnation so emphatically that it deserves mention. A double-track railroad tunnel was driven by the Northern Pacific Railroad near Tacoma, Wash., in 1912 and 1913, through heavy clay and sand

wet enough in places to have "a tendency to flow around the breast boards into the heading".* This tunnel was excavated behind a roof shield, and was timbered with segmental sets of 12 by 12-in. timbers, placed on 2-ft. centers, and lagged on the outside. Each set consisted of eleven segments. The lining proved entirely stable, and required less than 20 ft. b. m. per cu. yd. of material removed. Mr. Donaldson.

To return to Sections 8 and 9: it seems certain that, where a tunnel can be driven safely without timber, it is not good engineering to timber it. Segmental timber can be placed in short stretches as the excavation progresses, or after the excavation is completed if it seems necessary, and when placed it offers no obstacle to the construction of the permanent arch ring. Square-set timbering, on the other hand, must be placed as the excavation is removed, regardless of the character of the rock; it must fill the entire volume excavated, and consequently it will interfere to the greatest conceivable degree with the arch centering and the building of the arch itself.

A further objection to square-set timbering is this: the Lexington Avenue tunnels were driven so close to the surface that, even where the borings showed good rock, there was a likelihood of cutting a fissure filled with running ground and extending to some point below the roof line of the tunnel. Now if it is supposed that a bottom heading misses the fissure and that the next lift reaches it, the bottom will be neatly stoped out from under, and a run will be started that will stop when the soft ground gives out or the tunnel fills up. For an example, refer to the accident that occurred in driving the Mont d'Or Tunnel, under the River Bief Rouge, in 1912. This danger can be avoided by a top heading properly timbered to secure the roof. If necessary, the use of compressed air can be resorted to, as was done at 56th and 57th Streets.

Sections 10 and 11, between 79th and 106th Streets, included two general types of construction. The stretch from 79th to 98th Street was for the most part a double-deck tunnel, two tracks wide, with a steel lower story supporting a concrete arch roof. The rock, as Mr. Werbin states, "was fairly good, and very little timbering was used". The arguments just cited, bearing on the proper construction methods for Sections 8 and 9, consequently apply with equal force here. Certainly, the conditions and methods of excavation illustrated by Figs. 11 and 13 are as nearly ideal as the most grasping contractor could desire.

From 98th Street to the end of Section 11, the tunnel varied in cross-section, but was characterized by a flat roof supported by steel bents on 5-ft. centers, with rows of columns between the tracks. This is a type of construction to which segmental timbering is entirely

* *Engineering Record*, February 7th and 27th, 1915.

Mr. Donaldson.

unsuited, and ordinary timbering methods can be used to advantage only if the rock is so solid that it will sustain itself without support over a flat roof at least as wide as a one-track structure. The contractor, nevertheless, attempted to continue the plan that had been successful on other parts of the work, and kept his air shovel working until unsound rock north of 100th Street stopped him. A heavy and elaborate system of timbering failed to prevent large over-breakage in the roof. It was considered cheaper to take down loose rock above the roof line than to hold it in place, and at one point 12 ft. of rock were removed. Large quantities of excess concrete and dry packing were required.

The writer believes that from 98th to 103d Street, square-set timbering could have been used advantageously in the manner that Mr. Moulton suggests, and that the contractor could have saved money by using it. The cost, however, would probably have exceeded the higher figure given by Mr. Moulton, namely, $5 per cu. yd., due partly to the difficulty of organizing the job in New York City, but chiefly to the fact that the volume of rock removed in drifts and cross-cuts would have been much greater in proportion to the total volume than is the case in mining. Mine slopes are comparatively high and narrow, but these flat-roofed tunnels were low and broad.

Mr. Werbin.

ISRAEL V. WERBIN,* ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Moulton's discussion has perhaps set many to thinking of the possibility of adapting mining methods to excavating tunnels for engineering construction. The suggestions made by him are undoubtedly interesting, but, as one who has been intimately connected with the work described, the writer must take exception to his conclusion that mining methods could have been used advantageously on certain parts of the work.

Referring to the large double-deck tunnels, with a cross-section approximately 40 ft. square, Mr. Moulton states:

"The work on these sections presents problems more nearly comparable to metal mining than those encountered anywhere else on subway construction in New York City."

The mistake is made right at the start in assuming that there is any similarity between metal mining and the work described in the paper. There were several important factors connected with the work in question which eliminated any possibility of using any of the methods suggested by Mr. Moulton, and these were:

(1) That the work was done under narrow streets, in built-up sections of the largest city in the world;

(2) That the tunnels were driven dangerously near the rock line;

* New York City.

(3) That the rock was known to be of a dangerous character; and
(4) That the problem was not merely one of making an excavation, but of doing this so that there would be absolutely no settlement of the street surface, and, most important of all, of building a structure inside of the finished excavation.

Mr. Werbin.

Surely none of these problems is to be met in mining work, particularly if credence is to be given to the occasional newspaper reports of large areas adjacent to mining operations settling, on account of the work done beneath them.

Mr. Moulton criticizes the use of the top heading as being antiquated and expensive. This manner of attack is followed almost everywhere in tunnel operations in America. This fact may not perhaps make it the better method, but there were other important considerations which made it the only practical method to use on work of this kind.

The tunnels in question were driven in connection with subway work, and, from the point of view of economy of construction, it was desirable to keep the structure as near to the street surface as possible. The importance of this feature will be realized when it is noted that the cost of the excavation in such work is approximately 50% of the cost of the entire construction. It is also important, from the standpoint of operation, for the railroad at the stations to be as near to the street surface as practicable, so as to reduce to a minimum the height of the stairs, and to dispense with the use of elevators.

When the first subway in New York was built, a portion on upper Broadway was built in a deep tunnel, and access to the stations at 168th, 181st, and 191st Streets is obtained by using elevators. Experience shows that with the large amount of traffic handled by the city railroads, the use of elevators is not only an expensive feature of operation, but is highly undesirable. For this reason, on the new work in the double-deck tunnels on Lexington Avenue, the express stations were placed immediately beneath the local tracks, so that communication with the local stations could be had by short stairways instead of elevators. In order to maintain reasonable grades, it was necessary to keep the express tunnels a short distance below the local tracks. If a bottom heading had been used, good rock (not requiring any timbering) would have been encountered all along the line, except for a stretch of about 200 ft. at 74th Street. There were, however, several places along Lexington Avenue where old watercourses ran across the line of the subway structure, and at these places the surface of the rock was considerably below the roof line. The material directly above the rock at these points was a fine quicksand or alluvial earth, which, when encountered, was very difficult to hold and keep from being washed into the excavation.

Mr. Werbin.

Under such conditions, the use of a bottom heading would have been dangerous. The top heading had the advantage of acting in the nature of an exploration tunnel, so that the contractor was prepared in advance for the conditions with which he had to deal. When bad ground was encountered, it was taken care of by timbering, with or without lagging boards, as might be necessary; and, when the overlying material was once properly caught up and held, the element of danger was practically removed. Assuming that under such conditions the work was conducted with a bottom heading, it would mean that a very expensive system of timbering would have been necessary every time another lift was taken out, with the continuing possibility of the danger and damage that such an operation would have involved.

It must be borne in mind that the structure for the local tracks had been completed in advance of the express tunnel excavation, this being necessary in order to maintain necessary progress in the work. The loss of any material between the local structure and the express tunnels, therefore, would involve damage to the completed local track structure, in addition to settlement in the buildings at the street surface. It might also be mentioned that the contractor was held absolutely liable for all damage to buildings that resulted from his operations, irrespective of the matter of negligence, so that a procedure which would reduce to a minimum the possibility of damage might ultimately prove the most economical, even though some other method might permit the removal of the excavation more economically. When these matters are considered, the writer is sure that no mistake was made in using a top heading.

Mr. Moulton claims that with the methods of timbering ordinarily used in metal mining, it would be possible to work more nearly to the pay line of the excavation. The writer fails to see how the method of timbering can in any way affect the lines of excavation. This matter is determined more or less by the character of the rock and the way in which the strata lie. The writer believes that the men engaged on such works as that described in the paper are fully as competent as mining men to carry the excavation to approximate neat lines. The method of cribbing up the entire excavation might serve to hold some of the rock in the roof from falling down, but, as the writer has tried to bring out in the paper, no attempt was made to hold up such rock by timbering, the consensus of opinion being that the better practice would be to remove all loose rock. This conclusion was reached after careful study, there being little doubt that any timbering that would have to be put in to hold such rock in place, would be far more expensive than the additional cost of removing such excess excavation. The rock along the work in question had two seams running almost at right angles to each other, with the apex pointing upward, so that the rock in the roof was more or less wedge-shaped,

with the bottom of the wedge downward. The very dangerous condition is evident, and, when this rock persisted in working loose, even where timbering was placed, there was no doubt that it was good practice to remove these large masses of loose rock rather than attempt to hold them in place, where they would have been an ever-continuing menace to the lives of the men working in the tunnel. Mr. Werbin.

Mr. Moulton has criticized the segmental type of timbering as being expensive. The answer to this is that the problem was not only one of making an excavation, but also of building a structure inside the completed excavation. The square-set system of timbering used in mining, described by him, may be all right in a mine, but would make the cost of the construction that had to follow the excavation almost prohibitive. The subway structure could not have been erected without shifting considerable timber, and no engineer engaged on such work will deny that, once bad rock is caught up, it is very poor and dangerous practice to disturb the timbering.

The almost universal use of the segmental set in bad ground was prompted by the fact that, after it had been placed, the structure could be built beneath it with very little moving of the timbering. Another great advantage in the use of segmental timber in this work was the fact that, almost throughout the work, water was encountered in great quantities, and, by concreting between the timbers and grouting, a temporary roof was made. The water was then concentrated and led off through the grout pipes, and in this way was prevented from washing away the fresh concrete in the finished structure until it had had a chance to set.

The use of the longitudinal beams mentioned in the paper was not advocated so much on account of permitting any economy in removing the excavation, but solely because, with such a system, the posts directly under the sets did not have to be moved every time an additional lift was taken out; and it afforded a good foundation for the posts, irrespective of soil conditions. The beams and posting, therefore, could be placed where they would offer the minimum interference with the construction work that was to follow. The Lexington Avenue work was the first in which the large longitudinal beams were used to any extent, and the advantage of their use has been so marked that this system is being adopted on much of the more recent work.

Mr. Moulton has presented some data as to the estimated cost of making the excavation if mining methods had been adopted. He does not seem to have taken local conditions into consideration, and if, to the prices he gives, he adds the cost incurred by the contractor practically having no choice in the location and the number of shafts, the high cost that must be paid in the city for labor, plant sites, dumping privileges, superintendence and insurance costs, and the

Mr. Werbin. increased cost due to the drilling and blasting methods required in a job of this kind, the total sum for doing the work would be found to be higher than he apparently thinks it would be.

The writer is sure that, if Mr. Moulton had been familiar with the conditions peculiar to this work, he would not have advocated the use of square-set timbering, or conducting the excavation with a bottom heading. It would seem to the writer that the only place where such a method could have been considered would have been in connection with the tunnels of 100th and 102d Streets, where the spans were greater than 60 ft., provided very bad ground had been encountered. The large I-beams to hold up the roof in this part of the work were used by the contractor mainly so that he could continue to utilize his air shovel, but, as stated in the paper, this method of procedure was found to be very expensive, and of little advantage, so that the use of the air shovel was abandoned and the mucking was done by hand.

It was found possible to excavate the section for sufficient width to permit the construction of one track of the structure at a time without using any timbering whatever, except for occasional posting; and, after the structure for this one track was completed and the roof had been caught up, the excavation for the adjacent track was made.

It would seem to the writer that the method followed was better than to attempt to make the excavation wider and use timbering. The only objection to the piecemeal method of construction was the damage to the finished structure that resulted from carrying on the blasting adjacent to it, but this could have been avoided had the contractor taken proper precautions.

It might have been advantageous to use the methods suggested by Mr. Moulton, provided the rock encountered would not have permitted the excavation for one track with practically no timbering.

Paper No. 1389

A METHOD OF DETERMINING A REASONABLE SERVICE RATE FOR MUNICIPALLY OWNED PUBLIC UTILITIES*

By J. B. Lippincott, M. Am. Soc. C. E.

With Discussion by Messrs. Frank S. M. Harris, T. Kennard Thomson, W. B. Yereance, Leonard C. Jordan, H. F. Clark, Allen Hazen, W. G. Irving, H. A. Whitney, and J. B. Lippincott.

Synopsis.

The physical development of the Western States is far from complete, and although the larger municipalities may be able to finance utilities satisfactorily, in a manner commensurate with their needs, the growth, particularly of the outlying districts and smaller towns, will await largely the investment of private capital. In order to advance, all communities must have light, transportation, telephone service, water, etc. These utilities, whether privately or publicly owned, are essential to development. In California, at present, exclusive of steam railroads, 95% of the value of the public utilities is in private ownership.

In addition to the advisability of the public administration of both publicly and privately owned utilities being conducted on a fair and reasonable basis, it is essential that this administration should be such as will encourage the investment of private capital therein. If the rates for service of publicly owned utilities are too low, and

* Presented at the meeting of October 18th, 1916.

deficits are made up from the general tax funds, such administration is unfair to privately owned utilities, and will tend to discourage the investment of private funds therein, in States practicing this policy. Of late, and at present, in California, voluntary investment in privately owned utilities is awaiting the determination of public policy relative thereto.

The rates for service of a publicly owned utility should be fixed in the same manner as that for one privately owned, that is, it should be based on operation, plus depreciation, plus reasonable interest on value. Any surplus resulting from such administration should be deposited in the public treasury of the city to the credit of the general tax fund.

Public utilities are the framework on which the commonwealth is developed. All classes of citizens desire ready access to transportation, light, water, power, and telephones, in order to develop their communities economically. Excluding steam railways, 95% in value of the public utilities of California are privately owned. Statistical tables (Tables 1 and 2) show that not more than 10% of the State of California (after omitting the area of the desert lands south of Owens Lake) is developed as to density of population, and about 20% as to value. The wealth per capita is high. It must be borne in mind that the growth of a community, and its attendant wealth, are largely dependent on public utilities; and the investment of private capital in these enterprises should be fostered and encouraged with a view to the further growth of the State. A new and undeveloped State, such as California, manifestly cannot publicly build all its utilities.

There has been difficulty in obtaining the data on the relative value of municipally and privately owned utilities in California. That of the privately owned utilities for 1912 is taken from the report of the State Railroad Commission. This covered all the privately owned utilities, with the exception of the steam railroads, which have not been pro-rated for the different States. The best information on the municipally owned utilities is found in the report of the California State Controller for 1914. This report gives statistics relating to the municipal utilities in the State. For some of them, however, the values were not stated, and some were incomplete, as in the case of the Los Angeles Water Department, where the aqueduct was omitted. To

cover this latter item, $26 000 000 is added here. The values for the cities omitted are interpolated by computing the average value per capita for all the cities given and applying this figure to the population of the cities omitted. The Controller's report makes no mention of the San Francisco City Railways. These results are tabulated. Excluding the steam railroads, the value of municipally owned utilities is only 5.1% of those privately owned.

There is, of late, in the United States, a decided trend toward public ownership of public utilities, especially by municipalities. In California, both the Railroad Commission and the Courts have recently prevented privately owned public utilities from entering a municipality which is already being served adequately by another privately owned public utility of the same class. Yet municipalities of this State are exempt from such legal restrictions, and our highest Federal Courts have confirmed the right of the public to invade the field of a privately

owned utility in competition, without the legal obligation either to condemn or purchase the privately owned plants. The people have this inherent right to serve themselves, and though the public should be able to enjoy the profit and security of their own service, there is a broad equity involved that requires the protection of the privately owned plant which has been built in good faith and is being operated under public regulation so that its rates are just and its service adequate. It would be a public misfortune to confirm the impression that private investments are to be over-ridden unfairly and in such a way as to injure legitimate investment. If unfairness is practiced in our larger centers of population, having substantial bonding resources, it is apt to delay greatly the development of the back country, where public credit for large enterprise is lacking.

Rate-fixing commissions must be given credit for stabilizing the value of public utilities bonds. Stockholders have suffered severely, and in many instances they should. In California public utility corporation bonds, approved by State authority, are now sought after. The bondholders are usually only loaners of money. It requires stock buyers to build extensions and new works. The writer feels that it would lead to the more rapid development of the State if the Commission's policy were more liberal in the fixing of valuations, and especially in the permissible rate of interest return allowed. Private capital invested in utilities should be protected against unjust competition of publicly owned utilities. The building of private utilities in California has been practically stopped until it becomes more apparent what this public policy is to be. In Wisconsin this stage of State development has been passed.

In so far as known, neither the California Railroad Commission, nor the California Courts have ever expressed themselves as to what would be a reasonable rate for a publicly owned utility to charge its consumers. The Wisconsin Railroad Commission has reviewed this question, and the trend of its decisions is to the effect that the rate should be fixed in the same manner as though the utility were privately owned, the theory being that, where a publicly owned utility is in competition with one privately owned, it should not be given such preference as to result in the destruction of the value of the private plant. For instance, if a city goes into competition with privately owned plants for the sale of electric energy within its boundaries, and

the interest on the bonds and the sinking fund is paid from the general tax, it would put such a handicap on the privately owned plant as would ultimately work its destruction.

The rates for municipally owned utilities in California have often been fixed rather as a political, than as an economic, question, it being a popular and easy road to public favor to advocate the reduction of any rate.

The rate for a public utility service should be based on the fair value of the properties used and useful in the service, irrespective of whether the plant is privately or municipally owned. The municipal plant should be viewed as an investment of public funds by the city, and it should be operated with the view of obtaining a profit on the investment.

The rate for a privately owned utility should be adequate to provide, first, for the expenses of operation and maintenance, second, for depreciation, and third, for an interest return on the fair value of the property. This last item will provide interest on the bonded debt and any profit accruing to the owner. With a municipally owned utility, in addition to these expenses, there is a bond redemption fund. It has no counterpart in a privately owned plant, as its bonds are seldom retired, but, on maturity, are taken care of by a refunding process. In California, however, the law requires that municipalities retire one-fortieth of the bond issue each year.

There are four classes of people who should assist in bearing the cost of a municipally owned public utility:

First.—The city as a whole, or the government;
Second.—The consumer;
Third.—The owner of vacant lots;
Fourth.—The real estate promoter who desires extensions made to new subdivisions.

First.—The City's Share of the Expense.—The municipality should contribute from the general tax fund for the cost of all public uses of water, notwithstanding the fact that the origin of the fund is usually from the general tax budget. The city should also provide from the general tax budget the annual contributions to the bond redemption fund for the utility. If the municipality's credit has been used in the issuance of bonds for the purchase or construction of the utility

plant, then the refunding of these bonds from the general tax budget is virtually payment for the plant by the city as a whole.

Second.—The Consumer's Share of the Expense.—The consumer should, manifestly, pay for the operation and maintenance of the system, and, if the municipally owned utility is to be treated on the same plane with one privately owned, then it follows that the depreciation account and interest on the fair value of the property should be also charged to the consumer. To deduct from the rates the depreciation and interest would put such a handicap on competing privately owned utilities that they probably could not live. This situation, however, is one that cannot be treated by a hard and fast rule. For instance, if a municipality is looking broadly into the future for its public necessities, as is being done by the Cities of Santa Barbara and Los Angeles in the building of their aqueducts, and the depreciation and interest charges on these large expenditures are put solely on the present consumers, it may result in a rate that would prevent adequate and desired uses of the utility. Apparently, some latitude must be exercised in every instance, in determining how this distribution should be made, in order to obtain a rate which is a feasible operating one.

Assuming that the city can borrow money on its bonds at 5%, and that a reasonable service rate for the utility will provide interest on the fair value of the property at 7%, there accrues a 2% differential which is in effect the profit in operating the utility. This profit should be expended in the ordinary extensions and betterments of the system, so as to avoid the necessity for frequent bond issues to make these improvements. These, in fairness, should be paid for by appropriations by the city council from the general tax fund. However, those who have had to do with these matters know that such allotments of money cannot be obtained, as a practical working proposition. Only when a large and substantial improvement is to be made should it be done by means of a bond issue. If any surplus accrues from the profit of the system, over and above the expenditures for improvements and betterments, this surplus should be turned into the general funds of the city, for the purpose of reducing taxes rather than rates.

There are two classes of consumers under the municipally owned plant, those who are not taxpayers in the community, and those who are. The consumer who does not contribute taxes is paying a fair price for the service received, and is not entitled to have the cost of

this service reduced simply because he happens to be temporarily a resident in a community owning the utility. He has no investment there, and has assumed no liabilities on its account.

Property owners have guaranteed the payment of public debts. If the bond redemption fund is provided for from the general tax levy, all taxpayers are proportionate owners of the utility. A share of the profits accruing from this ownership should revert to the taxpayers through the general fund, so that the consumer who is a taxpayer receives an indirect benefit from the ownership of the utility in this way. This system would encourage property ownership.

Third.—The Vacant Lot Owner's Share of the Expense.—The vacant lot owner in our Western towns is a source of great expense and burden to all utilities. It is probable that one-half the mileage of distribution mains is caused by his speculation in land values. The utility is standing ready to serve at any time, and the value of the vacant property depends largely on its privilege to be benefited thereby. Unless a charge is assessed against vacant lot owners, they are securing benefits without adequate contributions to the expense of the plants. Some system of assessment on such vacant property on a front-foot basis should be developed to cover this element, as is often done in street paving and sewer work.

A portion of the cost of building the utility is borne by the vacant lot owner in that he is a taxpayer and has assumed the liability for the debts of the community. He enjoys the broad and general benefits that result from the operation and ownership of the plant, which the consumers alone should not pay for. There are many vacant lots in the old and established portions of the city where the plant has long been built, and such lot owners cannot be assessed as in the case of an extension to a new subdivision. Possibly they should be charged an assessment each year, which should go into a fund for ordinary betterments of the system or into the public treasury.

Fourth.—The Real Estate Promoter's Share of the Expense.—The real estate promoter is continually making new subdivisions and petitioning the utilities, whether publicly or privately owned, to make extensions therefor. With privately owned utilities it is usually demanded that the promoter shall pay for the cost of the extensions. This policy has also been followed in many of the publicly owned utilities, but it has resulted in political agitation, and has been vigorously

resisted by the interests who are active in their efforts to speculate on the community.

The vacant lands exploited by the real estate promoter may be divided into two classes: first, those lying within the corporate limits of the municipality owning the public utility; and second, those outside these corporate limits.

In the first instance it would be equitable to require the owner of the property to pay a frontage tax to cover the cost of the distribution system fronting the property in question, this contribution to be returned when this part of the plant is on an earning basis. It would not be proper to charge a portion of the cost of the mother plant against these extensions, because the property will already have paid some proportion of the cost thereof in taxes, and will pay more as its value increases. The assessments for the extensions to the new subdivision within the corporate limits of the city should be in the nature of a temporary donation.

If the lands to be exploited are outside the corporate limits of the community, it would again be just to require the owner temporarily to advance the funds necessary to make the extensions. So far as concerns storage reservoirs and conduit systems, or any of the mother plant built for the distant future, and which may equitably be assumed to involve the promoter's lands, a portion of the cost of this excess capacity should justly be charged to the promoter.

This whole problem cannot be solved rigidly with a rule which will apply to all cases. There is, however, the necessity for outlining some general theory, on which municipalities should proceed. Even if it is clearly defined, and is endorsed by high authority, there will be the practical political difficulties of fixing and maintaining rates at a just point. Obstacles will have to be overcome in case it is necessary to increase a rate. There is great inertia inherent in communities, and this it is necessary to prevail against, in order to make a change of any sort.

Our cities are becoming great business concerns, and should be managed fairly and scientifically, not only for the interests of the citizens therein, but also for those who have financed in one way or another their utilities and early development.

DISCUSSION

Mr. Harris.

FRANK S. M. HARRIS,* ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Lippincott has taken a thoroughly commendable stand in insisting that municipalities enter a public utility field which is more or less adequately served by a privately owned utility under rate conditions equivalent to those confronting the private enterprise. It is only as a result of such an equitable attitude that private capital may be expected to "pioneer" in those fields into which the public is not for the time desirous of entering. It is decisions such as that in the hearing of the City and County of San Francisco in the matter of special crossing privileges for its Municipal Railways,† in which the municipality was reduced to the standing of a private corporation, which have operated to remove the bitterest of the criticism heaped on the heads of utility commissions by the public service corporations which have been "regulated".

The writer has but recently completed an exhaustive survey of the whole franchise situation for the City of Oakland, Cal., in the course of which there was indirectly revealed the devious if not perilous path traversed by the average public utility company prior to 1900. The manifold injustices, at the hand of shifting political régimes under which they labored, were but equalled by the corrupt advantage which they in turn took of the municipality. It is refreshing, therefore, to find set forth so fair a basis for square dealing between the municipality and the private corporation.

Mr. Lippincott, however, considers only the case in which the municipally owned utility exists side by side with, but completely independent of, the privately owned utility.

Of late years, an innovation is being written into the franchises of privately owned utilities, in which the municipality is an active partner in all development and extension programmes, as well as in the formulation of financial and operating policies. Such a provision is but a corollary of the principles advocated by Mr. Lippincott.

For the new blanket resettlement franchise, now being sought by the San Francisco-Oakland Terminal Railways in exchange for its 130 or more parcel franchises, the following provisions are found:

(1)—A board of control composed of one representative of the city and one representative of the company shall have jurisdiction over such matters as extension, outlay for equipment, allowance for depreciation, and the like; and

(2)—After payment of operating expenses, taxes, depreciation as fixed by the board of control, and a 6% return on its agreed

† Oakland, Cal.

‡ *Engineering News*, Vol. 74, p. 181.

Mr. Harris.

physical valuation, at least 55% of the net revenue remaining shall be paid to the city.

These clauses are in addition to the usual machinery of the indeterminate franchise, providing for the taking over of the ownership by the city on 6 months' notice at the agreed physical value.

It would seem that, until such time as public ownership is the accomplished fact which it now bids fair rapidly to become, either an equitable rate-making policy for the municipal competitor or an implied co-operation between the municipality and the privately owned public utility are the essentials of any thoroughly satisfactory solution of the existing difficulties.

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—Mr. Lippincott deserves the thanks of the Society for his very clear presentation of a most vital issue.

We are going through a formative stage at present with such subjects as socialism, suffragettism, unionism, public ownershipism, anarchism, and general radicalism, and the tendency of the country is to try everything, even including Wall Street speculation; but, fortunately—like an intelligent child who has burnt his fingers—the country profits from the expensive experience, and tries something else. For instance, a town will elect a Socialist mayor, and then snow him under at the next election. Again, a State will try the "referendum and recall", pass a dozen different and contradictory bills on the same day, and then try to recall both the "recall and the referendum". The experiments which prove profitable will remain, and even a few, like suffrage, will undoubtedly stick, if adopted, whether really beneficial or not.

When it comes to public ownership, we have examples in New York City—the Staten Island Ferry, Brooklyn Bridge, etc.—which, as everybody knows, are not financially profitable. Even the Rapid Transit would not pay if entirely owned by the municipality. For what city would dare to pay a yearly salary of $100 000 or more to one man, even if he could earn many times that much for the taxpayers.

Ninety-nine men out of a hundred will say that no man is worth more than, say, $10 000 a year, and that he (that is, the other man) has dozens of men under him who could do the work as well or better for less money; and this in face of the facts found actually all over the world, for it is hard to make people believe what they see.

To take a single example: The Intercolonial Railroad, one of the best built railroads in America when constructed by the Canadian Government, enjoyed an absolute monopoly between Halifax and Quebec for many years. True, the country was largely undeveloped,

* New York City.

but not as much so as the vast Canadian Northwest was when the late Sir William Van Horne finished the Canadian Pacific Railroad; but Van Horne saw to it that the great prairies were developed to build up his road; whereas the men who ran the Government-owned Intercolonial stuck strictly to the business of operating the road, instead of creating business to make the road pay, with the result that for some 40 years the road did not even earn operating expenses, let alone pay taxes or interest on the money. Mr. Thomson.

The speaker, when recently talking to a prominent Canadian, suggested that, if the Government had engaged a man like the late Sir William Van Horne, or the late James J. Hill, F. Am. Soc. C. E., or any one else of that caliber, and offered such a man a salary of, say, $50 000 plus a bonus, he would have earned his salary, a bonus of several hundred thousands a year, after having paid the Government ample taxes and a good interest on the money invested in the railroad, and, at the same time, would have developed the adjoining territory, thus benefiting the country from one end of the Dominion to the other.

My friend contradicted me, saying that the Government at one time really did engage a man capable of getting these results, and that he at once began by examining the freight rates, which disclosed the fact that many of them were ridiculously low. He ordered the rates raised and made the same for all. To make a long story short, his days were numbered, and the road ran on as before.

On repeating this story to a very powerful newspaper owner, the speaker was told that such a state of affairs was quite justifiable, because it paid to run a road at a loss for the sake of building up the country. This, however, is exactly what such management never does, as it considers its duty done when it operates the road.

This is no reflection on the staff of this railroad, which is a very competent one, whose work is well done—that is, as far as it has any authority to work—but one man with the necessary power, and inducement, could take the same staff and turn a financial failure into a great financial success, thereby benefiting the entire country.

To take another example, nearer home; a fatal mistake was committed in the construction of our magnificent $150 000 000 Barge Canal (with political "poorsight") in the beginning when it was made a barge canal, instead of a ship canal. As it is, no boat with a clearance of more than 15 ft. above the water can pass under the bridges and use the canal. This mistake was not made on the Canadian canals, which, with the same or less depth of water as the Barge Canal, are able to pass vast fleets of masted vessels.

It now remains to be seen whether the same lack of judgment will be displayed in the operation of the Barge Canal, as on this depends the profit or loss on the enormous sums paid by the people for this undertaking. If the canal is properly managed, the State will enjoy

Mr. Thomson.

far-reaching results. Moreover, if a man is employed who has the ability and is given the power to make business for the canal, as well as to see that it is properly operated, the State will be handsomely rewarded for the sums expended for the construction and maintenance of this work, which in many ways far surpasses the Panama Canal.

It is just as if the State were to build a number of huge skyscrapers and then trust to luck that the people would find, use, and pay for them. Needless to say, the privately owned buildings adjoining, run by wide-awake business men, who would go after their tenants, would be filled at once, while the State buildings would be nearly empty, and of course operated at a loss.

It seems to the speaker that by discussing actual cases more progress will be made than by the expression of purely theoretical opinions, and that the ultimate result will be proper Government regulation, instead of Government operation or ownership.

Last spring, at a political meeting, called for the purpose of explaining the extra $19 000 000 appropriation in New York State, the speaker, after the regular speakers had finished, begged to draw attention to the great difference between the City and State on the one hand, and an ordinary business organization on the other; the business man has to earn the money he spends, while the City and State spend the money which they force the tax-payers to contribute.

The speaker then pointed out two projects which, if encouraged by the City and State, would result in putting both on a business basis. The City and State would receive more than $30 000 000 outright and a rental of at least $2 000 000 a year, to say nothing of enormous indirect benefits. The projects are "A Really Greater New York", and a "New Niagara Falls, of 2 000 000 h.p."

Mr. Yereance.

W. B. YEREANCE,* M. AM. SOC. C. E.—The author has stated clearly some of the problems to be met in the municipal ownership of public utilities. It is assumed that he has contemplated as well municipal operation of those properties or plants. Of course, it may be, and so happens, that some properties are municipally owned but privately operated by private corporations.

An insolvent or mismanaged utility is a handicap to the progress of the community or district it serves. A utility should be in receipt of a sufficient revenue to meet, under proper management, all operating expenses (including maintenance, depreciation, taxes, and a sufficient reserve as insurance against catastrophe), and a reasonable return on the fair capitalization of an adequate plant. This revenue is or should be produced practically in its entirety by the rates charged for service. Rates are or should be determined so that each beneficiary contributes to the total necessary revenue of the utility only his just

* New York City.

and due proportion for benefits received. If the plant be ill-adapted to the community's needs, or unnecessarily expensive, or the management extravagant or incompetent, or the securities inflated, the rates to produce the needed revenue will be unnecessarily high or unreasonable, either throughout or for certain classes of the service. Therefore, if minimum rates are to be enjoyed, the property or plant furnishing the service must be designed and constructed wisely and economically and operated efficiently. To the extent that these conditions have not been met, the rates will be above a possible minimum. Mr. Yereance.

For a given standard of plant and service in a given community, the rates for that service should be lower under municipal than under private ownership and operation. Yet, despite some highly flattering operating statements issued periodically, the speaker knows of no situation on this continent to-day where municipally operated utility service is being rendered at actually lower rates than are or should be charged for similar service by private enterprise. If politics and political considerations can be eliminated in the development and operation of a public utility, then and then only will be possible the successful establishment of actual rates that to-day are merely a dream of the theorist. Evidence is not lacking that there are those who realize the situation, and it may be that at some future period the ideal will be realized. However, those now interested in the private administration of public utilities need have no fear that their retainers or jobs are in immediate danger. If that ideal time comes when the public utilities can be removed from adverse political influences, then public utilities should be municipally owned and operated. Private enterprise has its own problems to meet in the conduct of public utilities, but it could not live under many of the practices now associated with municipal ownership and operation.

The author has referred to the inherent right of a community to serve itself, but calls attention to the broad question of equity involved where such contemplated municipally owned and operated service would introduce competition with a private plant, established in good faith, and serving the public adequately at reasonable rates. Some regulatory bodies have recognized the ethics of such a situation in their decisions, and the demands of simple justice—to say nothing of policy—have been met; other commissions have not been so far-sighted.

Some 3 or 4 years ago a campaign favoring municipal ownership was waged vigorously by some of the ambitious politicians in one of the Southern States. At that time the speaker was retained to protect a considerable investment of northern money in a combined electric light and gas property in one of the cities of that State. The electric plant was probably the most up-to-date of any in a community of that or considerably larger size in the United States; the gas

Mr. Yereance.

plant was not in quite such good shape, but both were fully adequate, and the rates charged were lower than prevailed—under Commission authority and at some places under more favorable conditions—in any community of similar size in that or adjoining States. The good faith of the investors was apparent in both the condition of the property and the amount of money actually invested, yet the political elements favoring municipal ownership practically forced the company into a desperate position, whence it was extricated with the greatest difficulty.

The attitude of the commission, the public press, and many of the people, was such as to discourage the investment of outside money in that locality; some are now beginning to realize the short-sightedness of that attitude when new money is desired but not procurable. Certainly, in the light of these facts, no honest consultant could or would recommend investment where such conditions prevail.

Reference has been made to a certain steam railroad, governmentally owned and operated. Located through thin traffic country, its value would seem to be largely military rather than economic. Such property needs a higher grade of management than does one which is more favored; yet the road in question has always been notoriously politically mismanaged. It could have been operated better with one-half the number of men shown on its pay-rolls. Instead of the two or three—as mentioned by Mr. Thomson—there were at least ten times that number of good railroad men in the United States who, with free hands, could have developed the full earning capacity of the property.

Mr. Jordan.

LEONARD C. JORDAN,* ASSOC. M. AM. SOC. C. E. (by letter).—A perusal of this paper conveys the impression that the author is in favor of private ownership of public utilities, and that he is even willing to go beyond the bounds of justice in hampering municipal ownership. The writer agrees with the author in advocating private ownership of public utilities wherever such a course is advisable, but he begs leave to differ with him in one or two of the points to be mentioned herein.

The author has brought up the matter of the status of the owner of vacant lots and his responsibility to the community, so far as respects his advantages from public utilities. It is quite true that he has distinct advantages in the increased value of his holdings, and it is equally true that he has been an important factor in running up the cost of these utilities by causing them to extend their service lines past his unused property, in order to reach the used property of other owners, the people who, by making use of the utility, furnish the revenue which keeps it in existence and on a profitable basis. However, there is probably greater likelihood of general all-around

* Morsemere, N. J.

Mr. Jordan.

justice in this respect when the utility is owned by the municipality, for, in the case of the municipally owned utility, the expense is met largely by assessment against the abutting property or by taxes on property in general. In the case of a privately owned street railway, for instance, the owner of the vacant lots very probably would fall heir to all the latent benefits of the railway without the expenditure of a single penny. Furthermore, his neighbors must pay, by the revenues from their fares, his share of the expense of construction and maintenance, as well as for the unwelcome privilege of being hauled past his unsightly and weed-covered property. Although the author advocates private ownership, this problem which he introduces would seem to be regulated more justly for all concerned when every utility is publicly owned and properly managed.

There is a contradiction of principle cropping out at various places in the paper, which is summed up very concisely in the Synopsis, as follows:

"If the rates for service of publicly owned utilities are too low, and deficits are made up from the general tax funds, such administration is unfair to privately owned utilities, and will tend to discourage the investment of private funds therein, in States practicing this policy."

Then a few lines farther along:

"Any surplus resulting from such administration [municipal ownership] should be deposited in the public treasury of the city to the credit of the general tax fund."

If it is proper to turn a surplus into the city treasury, then any deficit from operation should be remedied by drawing on the general city funds. Probably a correct business system of managing a municipally owned utility would include the keeping of strict accounts of all money matters pertaining thereto, as though it were an industry in itself and distinct from all other parts of the city government. The city treasury should be regarded as a bank, lending money to tide over unproductive periods, accepting surplus funds on deposit, and handling the bonds when their issue is required by unusual construction or development expenses.

Again, on pages 420 and 421 the author advises the charging of rates higher than the nature and business of the utility would justify and the turning of surplus amounts into the city treasury. It is argued that this method is fair to the taxpayer as it reduces his taxes on real estate. The writer is unable to see any justice in placing a burdensome portion of the expense on the poorer people of the community, in order that the property owners may enjoy the advantage of reduced tax rates. Such procedure would tend to break down democracy, in that it places obstacles in the way of the poor man and makes

Mr. Jordan.

easy the way of the man who already is rich. It is stated, relative to this matter, that the non-taxpayer is paying a fair rate for the services received, even though he is paying for a portion of the taxes of his more fortunate neighbor, but the writer fails to detect much fairness in the plan. We might as well have municipal ownership of grocery stores, charge the high rates that would be possible under such non-competitive business, and then attempt to square matters by cutting down the taxes of those people who happen to own their homes. It is far more just, for the individual and for the community in general, to let each man pay his own way as he goes, than to attempt to equalize high rates for trolley rides and for electric lights by reducing the taxes on the same vacant lots which cause so much extra expense to utilities by increasing the length of their service lines.

The writer believes that a fair and strict accounting of the construction and operating costs of publicly owned utilities would furnish sufficient argument to convince the most stubborn that private ownership is the best plan under present conditions. He would go further in the accounting, however, than is generally done. When summing up the construction costs, all contributing factors should be included, just as they would have to be if the work were being carried on by a private company. This would require that salaries, office rent, and other expenses of public officials connected with the work be included in the bill. It would require also that depreciation of equipment and interest on its investment be reckoned, and that interest on the cost of plant and on invested construction expense be computed and included.

In compiling the accounts of the cost of operation, likewise, every part of the cost should be hunted down and charged in the proper manner. If the city has a "Commissioner of Public Works", who manages the municipally owned water-works system, then his salary and a fairly computed office rent for his rooms in the City Hall should be charged against the operation of the water-works. Furthermore, if a quarter of the time of the city treasurer and his staff is required for collecting and handling the water rents, then a quarter of their entire expense should be charged against the water revenues; and, finally, the usual tax rate should be levied against the water-works, and the tax should be paid into the city treasury and charged against the earnings of the water department. This matter of taxing might seem to be superfluous, at first thought, but a moment's consideration should suffice to convince the reader that it merely means a transfer of certain figures from one account to another, adds a negligible amount to the cost of city government, and aids in showing exactly the financial condition of the water-works department. Such a plan of accounting would form a correct basis for the regulation of rates, and would be entirely fair to the private owners of rival systems.

Mr. Jordan.

Besides, the strict business system would furnish an incentive to efficient service on the part of the men employed in the department.

As a further example, a battleship is constructed at a Government Navy Yard for a certain figure, while a shipbuilding company builds the sister ship on contract at a greater stated cost. The newspaper comments mislead some people into the opinion that the only lack of perfection in the Navy is its failure to construct both boats. Yet, if all costs were tallied, the total might result in a far different opinion. The figures for the Government-built boat should include:

All the costs of plans, including the salaries of officers who oversee the work of preparation;

Office rent for all men engaged on this work, even though they occupy rooms in a Government building;

All construction costs that would be encountered by a private company doing the same work;

Salary, keep, barracks rent, etc., of all marines doing police duty in and about the ship until she is put into commission, and this item should include the expenses of officers in command of these marines;

Reasonable rent for that portion of the navy yard that is devoted to the job, or else interest, depreciation, maintenance, and taxes on the portion used;

Interest on the investment, depreciation, and maintenence of the equipment used;

Salaries, office rent, and other expenses of all officers and men connected directly or indirectly with the work;

A portion of similar expenses for all men whose duties are divided between this and other jobs, even including the Secretary of the Navy, if a portion of his work may be regarded as arising from this source;

Interest on all the foregoing amounts, computed to the day that the boat is finally put into commission;

And all other items, great or small, which directly or indirectly contribute to the amount which the Nation must finally pay for the battleship.

Some of these items are not included in the stated cost of the boat built by contract, but they should be added. The justice of a complete cost-keeping system will be realized when the reader considers the possibility of the purchase of a finished battleship from a foreign country or firm, as several other countries have done within the past few years. Besides, the people should have a right to know the total amount which such a fighting machine is costing them.

It might be contended that the office rent of the Secretary of the Navy would seem unduly high if computed on the basis of the cost of

Mr. Jordan. the building in which it is located and the cost of operating that building. If that is true, then the people have a right to know that they need a new janitor in that building, or a new building superintendent, or else that they paid too much for the building originally. From another angle, if that office rent is higher than would be charged for suitable quarters elsewhere, then there is first-hand evidence that the department occupying these offices is not qualified to be placed in charge of a business requiring a high grade of efficient executive ability, such as a shipbuilding establishment. It remains that the people have paid for the building and are continuing to pay for its upkeep, and it would look like poor management on the part of the Government if there is no possible return on the first cost and running expense. Besides, failure to account for all such matters would be unfair to the contracting firm which is willing and anxious to put together a battleship for less money than it really is costing the Government.

The result of such complete cost-keeping methods as suggested would probably lead to private ownership of public utilities, such as the author seems to prefer, a private company having a monopoly of the patronage of the community and correctly regulated by just officials of the local government. This is the ideal form of service when both private owners and ruling officials are ideal; and let us trust that we may enjoy these conditions at some time in the near future. At least, let us hope that any owning or regulating on the part of the Government will be done better than it seems to be doing with any such work now. Meanwhile, with all fairness to all parties concerned, let those engineers who are in position to decide or to influence questions of municipal or private ownership of public utilities render their decisions with impartial judgment, having in mind the furtherance of principles of justice which too often are overlooked in such affairs.

Mr. Clark. H. F. Clark,* Assoc. M. Am. Soc. C. E. (by letter).—The author has presented views on a subject which engineers are now having to consider seriously. Where public utilities are owned by cities, it is generally found that the cities prefer to have their own way in determining how the costs of operation shall be spread, and rather resent the intrusion of scientific suggestions. The tendency is to better management of civic affairs, with centralization of power in one man or a small group of men. Engineers may yet be of some assistance to the budget makers of a municipality in determining the questions which the author has brought out.

Municipal ownership in California is steadily spreading, records for 1916 showing approximately fourteen transfers of water systems to municipalities. The aggressive element within a community generally lays siege to the water company until at last bonds are voted

* San Francisco, Cal.

and the water system is purchased. A feeling of security then comes over the minds of the people, as no longer will there be occasion for petty annoyances. The constant friction over service and rates is then passed, and, be the results profit or loss, there is always that true friend, the tax budget, to come to the rescue in times of need. A monopoly exists over the community when this competition is removed, and the city finds itself a sovereign in the matter of the regulation of this utility business. Mr. Clark.

Analysis of the paper involves accounting to a large extent. All are aware that the full cost must be met somewhere, it remaining to be determined how it shall be distributed. To bring out a little more clearly the distinctions which the author has made, Table 3 shows his distribution of the expenses.

TABLE 3.—DISTRIBUTION OF WATER-WORKS COST IN A MUNICIPALLY OWNED UTILITY.

Item of expense.	CLASS BEARING EXPENSE.			
	Municipality.	Consumers.	Vacant lot owner.	Realty promoters.
Maintenance and operation	Through taxes for public uses.	Through rates.	.....	.....
Depreciation	.....	Through rates.	.....	.....
Interest	.....	Through rates.	.....	.....
Extensions	.....	.....	.....	Through deposits.
Betterments	.....	.....	Through special tax.	.....
Bond redemption.	Through taxes.	.....	.....	.....

The author states that municipalities have an item of expense to bear, in addition to those expenses borne by a privately owned utility, namely, the redemption of bonds within a 40-year period. The author suggests that this redemption fund should be met in the general tax levy, and therein, the writer thinks, he is in error. Cities, admittedly, are enabled, through their credit, to borrow money about 2% cheaper than a private company can finance its operations. If the city makes a 7% interest charge, as would be granted to a privately owned utility, any profit resulting under the bond rate of interest could be laid aside to redeem the bonds. If the bond rate of interest is 5%, the differential of 2% compounded annually at 4% will approximately retire the bonds in 30 years. Thus, as a fact, there is apparently no additional expense, but, in the case of a municipally owned utility, merely one more division of the same gross expenses that would be allowed a private corporation in the same utility business. The author has suggested the possibility of a profit in the management of the utility. Occasionally, reports made from an audit of the books show profits,

Mr. Clark.

but it is rather the exception to conditions. The writer does not see why there should be any profits under the support of municipal ownership, if the rates are adjusted scientifically. It should not be the aim of a city to make its water consumers pay more than the cost of the service. Too often the consumers cannot even bear this cost, and part of it is carried under other accounts into the tax rate for the year.

Table 3 places on the consumers the depreciation charges. There is no more depreciation accruing annually in front of an improved residence lot than in front of adjoining vacant property, eliminating the item of service connections and meters. It is not clear to the writer why only the users of water should be burdened with the depreciation account, when the vacant property is increased in value, due to the presence of the main in the street. Municipal ownership is generally favored when the condition of the city as a whole will be benefited, rather than the individual condition of each consumer. Though it is true that, under a privately owned utility, the consumers have to bear this depreciation, yet it is fair, under municipal ownership, that the vacant property should bear equally with improved property this item of expense.

The distribution of the various items of cost would appear to the writer to be more equitable if as shown in Table 4.

TABLE 4.

Item of expense.	Class Bearing Expense.			
	Municipality.	Consumers.	Vacant lot owners.	Realty promoters.
Maintenance and operation	Through taxes for public use.	Through rates.	.....	.....
Depreciation	Through taxes.	.....	.....	.....
Bond interest	.....	Through rates.	.....	.....
Bond redemption	Through taxes.	.....	.....	.....
Extensions	.....	.....	.....	Through deposits.
Betterments	Through bonds or revolving fund.	.....	.....	.....

In California it has generally been found that the maintenance and operation expenses of a water utility will approxmiate 40% of the total expenses chargeable. By the foregoing classification, an analysis will show that the consumer divides with others about evenly with the remaining 60% of the expenses which occur.

However, the writer agrees with the author that no rigid rules can be formulated in this matter, inasmuch as there are so many local situations to be met, as is shown by occasional items in the newspapers. Not long ago, an article commented on the refusal of a water-works board to turn over a considerable sum of money to the general city treasury,

in order that the tax rate might be decreased. The reasons given for the refusal were that the money would all be needed for improvements, in view of a contemplated reduction in the minimum monthly charge for water, with correspondingly less revenue for the year. This minimum was already one of the lowest in the State, but yet it seemed advisable to that board to lower it still further. Again, in another city, lately adorned to attract visitors, the park department began to use enormously increased quantities of water, drawing heavily on the safe yield of the system. The water superintendent was at his wits' end to keep up with the demand, and was unable to make any showing for his department, on account of the extreme demand of the park department, which gave him no credit for the water used. Mr. Clark.

The abuses of the sovereign water plant management may be corrected in time by the application of principles such as the author has presented. There is great need for city officials to recognize just such principles.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—This paper is timely and important. It represents a swing back of the pendulum that was set in motion when it was decided that henceforth the work of corporations in certain lines should be considered as public and not private business, and that it should be subject to public control. Mr. Hazen.

The control of such corporations by public bodies is directed primarily and principally to the control of rates. The work of reducing rates in the interests of those served, formerly carried out occasionally by legislation or by Court action, is transferred to commissions created for that special purpose. The business is ordinarily expedited. It is handled by men who at least have the experience growing out of handling a considerable number of such matters. Regulation of the character of service also is undertaken, and though by no means as complete, something is accomplished.

Quite recently, perhaps since Mr. Lippincott's paper was written, another and far-reaching step has been taken; for, in one important case, Government regulation of wages paid to workers employed by such corporations is undertaken.

There is one matter, however, which cannot be regulated by Government; investors cannot be made to put more money into an enterprise, because better service is needed, or because existing rates do not furnish the money necessary, or because money is needed to pay increased wages.

When the reduction of rates and the imposition of other burdens on public service corporations has proceeded to a point where investors will no longer furnish money to carry out needed improvements, it has clearly gone too far for the good of the business and the community.

* New York City.

Mr. Hazen.

If conditions of regulation become such that private capital will not be supplied willingly to carry on the business, the only apparent way by which the public can control it further is to take over the undertakings by the right of eminent domain, and raise the needed money by taxation or by borrowing on the public credit.

It is to be noted that, in the course of the procedure which results in reducing a corporation's profits, the last step of profit reduction comes at a greatly accelerated rate, by reason of a condition which may be and probably often has been overlooked. When a corporation is making fair profits, its credit is ordinarily good, and it can borrow money at the lowest market rates. As its earnings are reduced to a point which reduces profit below normal—and, perhaps, threatens to wipe it out—the corporation's credit is impaired, and the rate at which money can be borrowed is increased.

If the profits are good, the first reduction in rates may not have this full effect, but, as reductions proceed toward the point of eliminating profit, the double effect is felt, and the final profit is reduced and eliminated quite as much by the increased cost to the corporation of getting money as by the direct loss in rates.

It is a conservative estimate that, as a result of the severe handling of corporations in some of our States in the last years, the ordinary rates which well-managed corporations have been compelled to pay in order to secure money to carry on this business, has been at least 1% per annum higher than it otherwise would have been.

To illustrate: If a corporation is earning 7% and borrowing money at 5%, it has a surplus of profit of 2%, which is a margin tending to make the business attractive to new investors and to maintain the corporation's credit. The margin is not wide, but it may answer. If in such a case, the gross earnings are 14% and the operation cost and taxes are 7%, and there is a reduction in rates, which effects a reduction in gross earnings from 14 to 13%, the direct effect is to reduce the net return from 7 to 6 per cent. The indirect result—which may not follow quite as rapidly, but is no less sure—is that, with the reduced margin to sustain credit, it is no longer possible to borrow money at 5%; and instead 6% must be paid, all the profit is wiped out, and the corporation is on the way to bankruptcy. A reduction of only 7% in the gross income may mean the difference between a margin of profit which will enable the business to be conducted successfully on conservative lines, and bankruptcy.

In the long run, the question of fair returns is boiled down to this: The returns must be sufficient to allow the business to be conducted successfully and permanently, and to permit everything to be done that needs to be done, including the securing of all new capital necessary for the reasonable extension of the business.

Mr. Irving.

W. G. IRVING,* ESQ. (by letter).—The writer has attempted to give due consideration to the conclusions expressed in this paper, but has no doubt that more study would be profitable. He agrees with the author that a municipally owned utility should be viewed in the same light, and should have the same restrictions and privileges, as a privately owned public utility.

The construction or operation of a public utility, such as waterworks, lighting works, etc., is not a municipal function. A city, as such, has no inherent right to engage in such forms of activity.

It is merely by special dispensation of the sovereign power that municipalities have been permitted to enlarge the scope of their powers to include the ownership and operation of utilities; and, in the operation of these utilities, with the exception of the fixing of rates, the municipality is impressed with the same obligations, as to service and as to responsibility for damages, as is a private owner of a public utility.

Therefore, the writer is of the opinion that the municipally owned public utility, in fairness to the privately owned public utility, should be under the same rate-fixing authority, and that the fixing of the municipal rates should take into consideration the same factors as are considered in fixing the rates of privately owned public utilities.

The writer, however, notes in this paper that the author has defined four classes of people who should contribute to the cost and maintenance of a municipally owned public utility. The writer is inclined to the opinion that this classification is arbitrary. No such classification is made with reference to privately owned public utilities. The city should either authorize a bond issue or make a direct appropriation from its funds, to provide the capital necessary to construct the utility. Then rates should be fixed by the constituted authority, to be charged the consumer for the service to be rendered, which should provide sufficient return to pay interest on the investment, cost of operation and maintenance, and to cover depreciation. There should not be, however, any amount allowed as a sinking fund to retire the bonds, if such are issued. The bonds should be retired by a direct tax on the taxable property of the city. As the bonds are retired, the interest payable thereon is decreased, and a greater proportion of profit of operating the utility should be paid into the general fund of the city which would permit a *pro tanto* reduction of taxes.

By this method, the owner of vacant property will be compelled to pay his portion of the cost of the system, and will also derive benefit therefrom, by reason of the enhanced value of his property and the ultimate reduction of his taxes by the profits earned by the utility.

* Riverside, Cal.

Mr. Irving.

The vacant lot owner, and all others who do not receive service from the utility, will also have to contribute to the maintenance of the system and to the payment of interest on bonds (if such are issued), during the adolescent period of the utility, as during that period the actual consumer cannot be expected to pay more than a fair rate, having in view the ultimate service to be rendered and the present capital expenditure.

By pursuing the foregoing method, a fair division of the general expenses of a publicly owned utility could be made, and, at the same time, it would prevent unfair competition with privately owned public utilities.

In the foregoing the writer has considered the question on general principles only, and has not had, and naturally could not have, in mind the many practical difficulties and scientific factors which would readily enter into the author's consideration of the question.

Mr. Whitney.

H. A. WHITNEY,* M. AM. SOC. C. E. (by letter).—Inasmuch as the underlying principles that go toward setting the service rate for one municipally owned public utility may be applied quite readily to all municipally owned utilities, the writer will confine his remarks to the utility of greatest importance, *viz.*, "the water department".

In order to estimate the annual charges against a water system thus owned, the following items should be known:

Schedule I.

(1)—The reproduction cost of the system, less the depreciation;
(2)—The annual depreciation of the system;
(3)—The annual cost of operation and maintenance;
(4)—The cost of business management (generally included in (3));
(5)—The amount of interest to be paid annually;
(6)—The amount to be set aside for new construction.

These annual charges will be divided into the following classes:

Schedule II.

Item 1.—Charges to the municipality; bond issues for construction;
" 2.—Charges to local improvement districts for local construction;
" 3.—Charges to the municipality to be paid from general funds;
" 4.—Charges to consumers for service installations and extensions;
" 5.—Charges to consumers for domestic rate;
" 6.—Charges to consumers for manufacturing purposes.

* San Francisco, Cal.

Mr. Whitney.

The principal advantages gained by a municipality in owning its utilities are:

Schedule III.

(1)—Lower interest rates than those generally allowed privately owned utilities;

(2)—Lower water rates to consumers, due to vacant property helping to pay for the bond issues, and other charges paid for by the municipality;

(3)—Privilege of having ample fire protection, and thereby getting:

(4)—Lower insurance rates;

(5)—Power of extending the system where it can do the greatest good to the greatest number of people.

The foregoing are generally cited by advocates of a municipally owned utility as benefits derived by the municipality which owns its own system. Although, in a good many cases, a low water rate can be obtained by the consumer at the expense of the entire city (it bonding itself to pay the sinking fund and interest on the cost of the whole system, and the construction being permanent), yet, as in the case of the City of San Diego, the city was quite willing to do this, as was shown in 1912, when, by a vote of 6 to 1, the city purchased the impounding system, and again, in 1914, when, by a vote of more than 5 to 1, it decided to purchase Morena Dam. Furthermore, the heavy taxpayers were all back of the project.

Santa Rosa, Cal., went even further than this, a few years ago, and, by a large majority, voted bonds to purchase and operate a water system—the consumers to have free water.

The total annual revenue and charges should be such that they will equal the last five items in Schedule I. A list of these charges is set forth in Schedule II, and will be taken in their regular order.

Item 1.—Charges to the Municipality; Bond Issues for Construction.—As a main trunk sewer, a main drainage canal in a municipality, or a trunk highway, is a benefit to a community as a whole, so should dams, main pumping plants, and transmission lines be so considered; and the costs should be paid by the municipality, by either a tax levy or a bond issue.

Item 2.—Charges to Local Improvement Districts for all Local Construction Which is not a Benefit to the Community as a Whole.—Under this item all distributing mains, service mains, local reservoirs, and stand-pipes would be assessed against the district benefited.

The following sections from Chapter 98, Sections 3, 5, and 15, of the Local Improvement Laws, State of Washington, for 1911, will illustrate quite aptly the privileges derived by being able to apply these laws. The following are extracts from certain portions of these laws:

Mr. Whitney.

Section 3 allows the city to provide for sewer, drain, and water systems, within or without the city limits.

Section 5 allows the city to provide for protection from fire by an auxiliary water system. Besides allowing the construction of the ordinary distribution system, the following paragraph allows the construction of drains of any size, either within or without the city limits.

"Section 15.—Any city shall have power to provide for the construction of trunk sewers, and trunk water mains, and for the payment of all or any part of the cost and expense thereof by the levying and collecting of assessments upon property specifically benefited thereby. In any such case the district created to bear such assessment shall be outlined in conformity with topographical conditions, and in case of trunk sewers, shall include as near as may be all the territory which can be sewered or drained through such sewer and sub-sewers connected thereto, and in case of water mains, shall include as near as may be all the territory in the zone or district to which water may be distributed from such trunk water main through lateral service and distributing mains and services. In distributing such assessments, there shall be levied against the property lying between the termini of the improvement, back to the middle of the blocks along the marginal lines of the street or area improved, such amounts as would represent the reasonable cost of a local sewer and its appurtenances, or a water main and its appurtenances suited to the requirements of such territory in the mode prescribed in Section 13 hereof, and the remainder of the cost and expense of such improvement shall be distributed and assessed against all the property within the bounds of said entire district in accordance with the special benefits conferred thereon and in proportion to area."

Under these local improvement laws, the City of Seattle and the City of Tacoma put in their distributing systems. Seattle uses only cast-iron pipe, and 8 in. as the minimum diameter. Tacoma uses 6 in. as a minimum diameter. The costs of all hydrants are assessed equally on the district.

Item 3.—Charges to the Municipality to be Paid from the General Funds.—Under this head will be:

(*a*) Charges to the fire department for the maintenance and operation of hydrants, and, where the cost of the system has been paid for out of water receipts, a charge should be made for overbuilding it from what would be necessary as a domestic supply to that of a "fire protection system". The only way to arrive at this proportion is to make a thorough study of the pressures needed, and the pipe sizes adequate for a domestic supply, and then place a value on the system thus estimated. Then calculate the cost of the water system necessary for an adequate fire protection, both as to pressure and supply. The difference in cost between a

system designed for adequate fire protection and one which is necessary only for a domestic supply, will be the amount on which the municipality should pay for interest, depreciation, and maintenance. Roughly, for a city of 50 000 people, the cost of fire protection service would constitute about 50% of the cost of the entire system.

(*b*) The school board should pay the cost of all water used in schools at the same rate as regular domestic consumers.

(*c*) The park board should pay, without any discount, the cost of all water used in parks.

(*d*) The board of public works should pay the cost of all water used for streets, sewers, or in any municipal department under its jurisdiction.

Item 4.—Charges to Consumers for Service Installations and Extensions.—In most cities a charge is made to a new consumer for putting in the house service and the meter. This is generally a fixed charge.

Item 5.—Charges to Consumers for Domestic Rate.—The domestic rate is generally ascertained, as a lump sum, by deciding that all other items shall be met out of the water revenue, and then adjusting the charges of the domestic and manufacturer's rates so that it will equal this amount.

Item 6.—Charges to Consumers for Manufacturing Purposes.—Items 5 and 6 are generally worked in conjunction with one another. After all else has been fixed, the revenue necessary to be derived from the domestic and manufacturer's rates can be determined. The only rational and satisfactory method of serving water to the public is by meter. Under a strict meter rate, it is known at all times how much water is being used and for what purposes. The Peoples Water Company, of California, serves the Cities of Oakland, Berkeley, Alameda, Richmond, Piedmont, and several small towns with water. The system is 100% metered. The writer had occasion to take from the books of this utility the quantities of water that were being used for various purposes in Berkeley during 1915, that city having about 12 000 service connections. It was found that, out of 100% of the live consumers, the distribution of the percentages were as shown by Schedule IV:

Schedule IV.—Percentages of Consumers Using Various Quantities of Water.

Consumers using	400 cu. ft. or less	.....	41.7%
" "	500 " " " "	.....	54.2%
" "	800 " " " "	.....	77.4%
" "	1 000 " " " "	.....	84.7%
" "	5 000 " " " "	.....	99.1%
" "	50 000 " " " "	.....	99.9%
" "	more than 50 000 cu. ft.	...	0.1%

Mr. Whitney.

The distribution of the various quantities is shown in Schedule V:

Schedule V.—Percentages of Quantities of Water Used.

Quantity	used,	up	to	and	including	400	cu.	ft.	15.0%
"	"	"	"	"	"	500	"	"	22.7%
"	"	"	"	"	"	800	"	"	42.0%
"	"	"	"	"	"	1 000	"	"	50.4%

"	"	in quantities of more than 50 000					"	"	7.0%

In setting rates in a municipality, it is often the desire of the community to have the water consumers pay a low rate, and do so, to a great extent, at the expense of the property owners. It often happens that there is, besides the municipal water department, a privately owned utility which serves the community with water, and, unless some provision is made to take care of the rates of the utility, in order that they may parallel those of the municipality, a discrimination will be worked on the privately owned system. In order to illustrate how to establish a low rate which will work fairly to both parties, the writer will assume a system designed for fire protection, the distributing system to be laid by local improvement districts, the collecting and transmission systems to be paid for out of the taxes or bonds, and the maintenance and operation, and emergency construction to be paid for out of the water receipts. The following data are assumed for illustration:

1.—Population	50 000
2.—Number of consumers	10 000
3.—Annual consumption, in cubic feet	200 000 000
4.—Percentage of water used per month less than 1 000 cu. ft.	23
5.—Percentage of consumers using less than 1 000 cu. ft. per month	54
6.—Percentage of water used per month, between 1 000 and 2 000 cu. ft.	27
7.—Percentage of water used per month, between 2 000 and 10 000 cu. ft.	31
8.—Percentage of water used per month, between 10 000 and 40 000 cu. ft.	9
9.—Percentage of water used per month, more than 40 000 cu. ft.	10
10.—Estimated present cost of system	$3 000 000
11.—Interest on bonds at 4½% per annum	$ 135 000
12.—Depreciation on system at 2%	$ 60 000
13.—Cost of operation and maintenance	$ 110 000

Mr. Whitney.

It is contemplated that the interest shall be paid out of the general tax on the system, and that the depreciation (either by sinking fund or otherwise) shall be paid from the water receipts, as will also the cost of operation and maintenance. This makes a total:

14—For depreciation, and maintenance and operation..	$170 000

Schedule VI.—Assumed Rates.

15.—For 1 000 cu. ft. per month or less.....	$1.00
16.—Cost per 100 cu. ft. from 1 000 to 2 000 cu. ft....	0.10
17.—Cost per 100 cu. ft. from 2 000 to 10 000 cu. ft....	0.7½
18.—Cost per 100 cu. ft. from 10 000 to 40 000 cu. ft..	0.5
19.—Cost per 100 cu. ft. for more than 40 000 cu. ft..	0.3

From Items 1 to 9 and 15 to 19, a table of rates (Table 5) has been compiled.

TABLE 5.—RATES OF RETURN, AS INDICATED BY ITEMS 1 TO 9 AND 15 TO 19.

54% of consumers at $1.00 per month (using 23% of the water per annum).....	$64 800
27% of 200 000 000 cu. ft. at 10 cents per 100 cu. ft. per annum.	64 000
31% " " " " " 7½ " " " " " " "	46 500
9% " " " " " 5 " " " " " " "	9 000
10% " " " " " 3 " " " " " " "	6 000
Total revenue.....	$180 300

Table 5 shows that the revenue amounts to an annual rate of $18 per consumer. If it is decided to construct $100 000 worth of improvements to the distributing system and $200 000 worth to the collecting and transmission system, the distributing system to be improved by a local improvement district, bonds at 6%, and the collecting and transmission system to be improved with bonds against the municipality bearing interest at 5%, we have:

$100 000 at 6%.....	$6 000
200 000 " 5%.....	10 000

Making a total amount borne by the city, as follows:

$3 000 000 at 4½% (as shown by Item 11).....	$135 000
200 000 at 5%	10 000
Total municipal bond interest.....	$145 000
Local improvement bonds.....	6 000
Maintenance, operation, and depreciation.....	170 000
Grand total for support of system.....	$321 000

Mr. Whitney.

Inasmuch as the expense of the bonds is borne by the municipality, this leaves only the maintenance and operation to be taken care of through the water revenues. The estimated revenue, as shown by Table 5, is $180 300, and the maintenance and operation being $170 000, there is left a surplus of $10 300 for emergency construction.

Some method should be adopted whereby the privately owned utility can charge a rate which will be approximately the same as that of the municipality, and at the same time pay a reasonable revenue to its owners. If it is the desire of the municipality that the water consumers shall have low rates at the expense of the taxpayers, it apparently should not matter (if the utility is serving as good water at as ample a pressure and in sufficient quantities as the municipality) whether the difference is paid by taxes on bonds against the municipal system or by taxes on the general funds to subsidize the plant of the utility.

An annual budget equal to the interest on the estimated cost of the privately owned utilities plant could be assessed against the general taxes and allowed to this utility as rental for the use of its system and the privilege of using the fire hydrants; the utility should be allowed to pay—as mentioned in the case of the municipality—the maintenance, operation, and depreciation expenses, from the revenue derived from the sale of water, this revenue to be regulated by the city council or other authorized body. Thus competition would be placed on an equal basis.

The foregoing is a suggestion as to some of the ways in which revenue might be derived. Numerous modifications of these methods may be made, such as charging rentals for hydrants, street sprinkling, sewer flushing, etc. Inasmuch as all of these are paid for from monies derived from the general taxes, it amounts to the same in the end. Then, too, the revenues may be increased to the extent of having the department pay the expense of construction.

By the methods outlined herein a municipality can set a rate which will place as small or as large a burden on the water consumer as may be desired. The water must have a fixed cost, and what the consumer does not pay the taxpayer must.

Mr. Lippincott.

J. B. LIPPINCOTT,* M. AM. SOC. C. E. (by letter).—Almost without exception, the discussion brought forth by this paper agrees with the writer in that the service charges for a publicly owned public utility should be fixed on the same basis as those of a privately owned utility which is subject to rate regulation.

Mr. Harris has indicated the basic element when he says:

"It is only as a result of such an equitable attitude that private capital may be expected to 'pioneer' in those fields into which the public is not for the time desirous of entering."

* Los Angeles, Cal.

Mr. Lippincott.

It is not only that the present investment of private capital in public utilities should be protected, but that the policies adopted be such that the further investment in utility enterprises in undeveloped communities be fostered and encouraged by the assurance that these investments have the sanction and protection of legislative bodies. Mr. Yereance has also called attention to this point. Mr. Yereance and Mr. Thomson have discussed to some extent the relative merits and efficiencies of municipally operated utilities as against those privately operated, from which conclusions are drawn that it is difficult to obtain in municipally operated plants competent executives. It is generally not possible to pay salaries adequate to obtain the services of such men, and the executives are so hampered and tied with the red tape of municipal and political organizations that effective results are not generally obtained. Because of unreasonable abuse it is not a sufficient honor to hold a municipal office. Although this may be the general rule, yet some notable exceptions have come under the writer's observation. The Water Department of Los Angeles is most efficiently organized and operated. Santa Barbara and Long Beach, Cal., both own and operate their water-works. The management is efficient, and the earnings of the departments show a substantial profit.

Mr. Jordan's discussion is more fanciful than consistent. The relative merits of private or municipal ownership of public utilities is not at issue. The effort has been made in the paper to apportion the expense of a publicly owned utility so that each member of the community will carry his proportion and that private enterprise may not be discouraged. The segregation of the expenses is largely a matter of judgment.

Mr. Clark suggests that the consumers should pay through their rates only for the maintenance and operation of the system and the interest on the bonds, the depreciation being derived from the general tax levy. Relative to the redemption of bonds, Mr. Clark also states:

"If the city makes a 7% interest charge, as would be granted to a privately owned utility, any profit resulting under the bond rate of interest could be laid aside to redeem the bonds. If the bond rate of interest is 5%, the differential of 2% compounded annually at 4% will approximately retire the bonds in 30 years."

In the writer's classification of expense accounts, the effort has been made to create a service rate which would be in harmony with that for a privately owned utility. Under Mr. Clark's segregation of expenses, the service rates would be below those which could be profitably charged by a private corporation. Rates for privately owned utilities are fixed with a view of yielding the owner a fair profit on his investment. If this is done with a municipally owned plant the "fair profit" could be turned over to the general tax fund of the city. If the bond redemp-

Mr. Lippincott.

tion fund is paid from the general tax levy and the profits accruing from the operation of the system are paid into the general treasury of the city, it appears to the writer that the same end is achieved whether the bond redemption fund is carried by the utility department itself or by the city at large.

There is a surprising tendency constantly to put more burden on the property owner and less on the thriftless individual, whether that ownership be of realty or of a utility. The result tends to discourage investment in enterprise and to encourage indolence. Mr. Irving and Mr. Clark both consider that the owner of vacant property should be exempt from any special tax due to the utility other than that imposed on the city at large. It is the writer's contention that the benefits derived by the owner of vacant lots, because of the fact that the service of the utility is immediately available, is out of proportion to the charges on the property through taxes, and that, in addition to these charges, the owner should pay a special tax, probably on a front-foot basis. These fees should be considered as an addition to surplus, and could be turned into the general fund of the city. They have no counterpart in a privately owned utility, and would operate to the benefit of the community at large. Mr. Clark states: "It should not be the aim of a city to make its water consumers pay more than the cost of the service." It appears to the writer that a municipally owned utility should be viewed as a community investment and should be operated at a profit in the same way as a corporation is operated for the profit of its stockholders. The property owners are in effect stockholders in the municipal plant. Mr. Clark's contention concerning the depreciation of pipe lines in front of vacant property is true. Rate regulating bodies in California have adopted a practice of reducing the capital and depreciation accounts of private utilities where they appear to be overbuilt. Some such system might be adopted here to relieve the consumers from the depreciation charges for mains paralleling vacant property, and these charges might be made up from the proposed special tax on vacant lots.

Mr. Whitney's segregation of expenses is extremely interesting, and appears to the writer to be entirely logical. However, in the case of the competing private enterprise, it is doubtful if municipal legislative authorities would consent, possibly for political reasons, to the inclusion in the annual tax budget of an assessment to cover interest on the value of a privately owned plant.

Although it is not proposed to review the procedure of rate regulating commissions for private utilities, the writer might add, to what Mr. Hazen has said, that these commissions would increase their economic value to the community if they evolved a plan under which a premium was placed on efficient management of the utilities coming under their jurisdiction.

Mr. Lippincott.

In closing the writer wishes to express his appreciation of the discussion called out by the paper. He feels that the public welfare would be better served if policies were adopted by those in authority in legislative positions which would encourage and foster the further investment of private capital, particularly in those States which are in a formative or developing process. It should be kept well in mind that legislation or Court decree cannot compel the independent investor who is seeking new enterprises to enter fields where others already operating on such lines are losing money due to unfair competition.

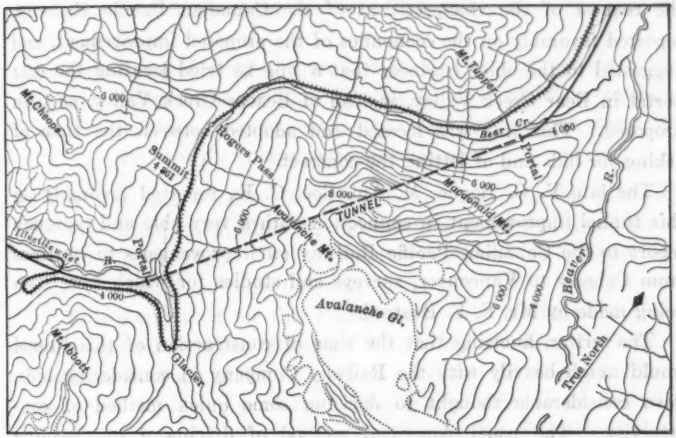
Paper No. 1390

CONSTRUCTION METHODS FOR ROGERS PASS TUNNEL*

By A. C. Dennis, M. Am. Soc. C. E.

With Discussion by Messrs. E. Lauchli, Robert A. Shailer, R. H. Keays, F. Lavis, James F. Sanborn, Lazarus White, T. Kennard Thomson, Francis Lee Stuart, J. V. Davies, S. A. Knowles, R. E. Dougherty, C. R. Hulsart, J. G. Sullivan, and A. C. Dennis.



Synopsis.

This paper describes the construction of the Rogers Pass Tunnel, on the Canadian Pacific Railway, through the Selkirk Range, in British Columbia.

The principal feature of the paper is the description of the pioneer, or auxiliary heading, method of construction, by which: adequate ventilation of the headings was secured; the removal of the muck was facilitated; the water, air, and ventilation pipes were not subject to disturbance; it was possible to expedite the work of enlargement of the main heading; a route for men, tools, and materials was provided; and the ventilation pipes were carried around the drilling, blasting, and mucking operations in the main tunnel, thus preventing delays due to gas and smoke. The "pioneer heading" appears to have justified its use for this tunnel.

The Rogers Pass Tunnel is a double-track tunnel, slightly more than 5 miles long, being part of a local improvement, about 10 miles long, of the Canadian Pacific Railway Company's main line through the Selkirk Range, in British Columbia. The map and profile are shown on Fig. 1.

* Presented at the meeting of February 7th, 1917.

PLAN AND PROFILE OF ROGERS PASS TUNNEL

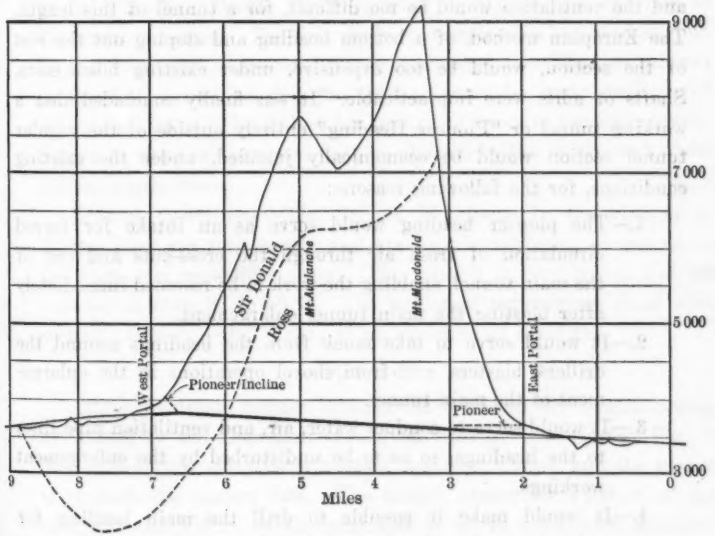


FIG. 1.

The writer visited the site of this tunnel in the fall of 1912, at the request of the vice-president of the Canadian Pacific Railway, reported favorably on the economics of the proposed improvement, and suggested to the chief engineer that a line be tried locating the east portal in Bear Creek Valley, instead of Beaver Creek Valley, as then proposed. This line was located and adopted between the time of asking for bids and of letting the contract.

The late V. G. Bogue, M. Am. Soc. C. E., reported favorably on this tunnel improvement in connection with a very able and thorough report to the Canadian Pacific Railway on improvements to its lines from Calgary to Vancouver, surveys and studies for which were then being made by Mr. F. F. Busteed.

The writer, knowing that the time of construction of this tunnel would weigh heavily with the Railway Company in considering bids, gave considerable thought to devising some quick method of construction. The usual American method of driving a top heading and taking out the bench with a power shovel was obviously too slow, and the ventilation would be too difficult, for a tunnel of this length. The European method, of a bottom heading and stoping out the rest of the section, would be too expensive, under existing labor costs. Shafts or adits were impracticable. It was finally concluded that a working tunnel or "Pioneer Heading" entirely outside of the regular tunnel section would be economically justified, under the existing conditions, for the following reasons:

1.—The pioneer heading would serve as an intake for forced circulation of fresh air through the cross-cuts and out of the main tunnel, enabling the work to be resumed immediately after blasting the main tunnel enlargement.

2.—It would serve to take muck from the headings around the drillers, blasters, and from shovel operations in the enlargement of the main tunnel.

3.—It would serve to conduct water, air, and ventilation pipe lines to the headings, so as to be undisturbed by the enlargement workings.

4.—It would make it possible to drill the main heading for enlargement far ahead of, and without interference from or with, the main tunnel blasting or mucking for enlargement.

5.—It would supply a route for men, tools, and materials to pass to and from the headings and enlargement drilling at all times.

6.—It would carry the ventilation pipe around the main tunnel enlargement drilling, blasting, and mucking operations, so that the gas and smoke from the heading operations would not foul the enlargement operations.

It was thus possible to keep the heading progress, enlargement drilling, enlargement blasting, and mucking going continuously, without any interference with one another whatever. Fig. 2 shows the relative location of these different operations.

Bids were asked for this tunnel work early in 1913, and the contract was let to Foley Brothers, Welch and Stewart, Railway Contractors, in June, 1913. This firm was not the lowest bidder, but undertook to do the work more quickly than other firms, its estimate being based on the proposed pioneer method, Mr. Stewart, of the contracting firm, and John G. Sullivan, M. Am. Soc. C. E., Chief Engineer of the Canadian Pacific Railway, being willing to take the risk of this untried method. The first study contemplated a top heading, but, at Mr. Sullivan's suggestion, this was changed to a location midway in the full section, so that the heading could be made smaller and still permit holes to be drilled far enough to break to the full section; otherwise, the work has been done as planned by the writer, and under his superintendence.

General Conditions.—The Selkirk Mountains in the vicinity of Rogers Pass are very rough, and are heavily timbered, except where the numerous snowslides occur. The rainfall is very heavy, and the snowfall is from 30 to 50 ft. The minimum temperature since work started has been — 32° Fahr., at an elevation of 3 800 ft.

Geology.

The approximate contact between the Ross and Sir Donald Series, as named by the Dominion Geological Survey, is shown in Fig. 1. The axis of this syncline is west of the West Portal, and the tunnel is through the eastern limb. The tunnel, except for 1 200 ft. of the east end and 400 ft. of the west end, is all in solid rock, classified as quartzite in the geological reports, but consisting largely of schists. The rocks contain no fossils, and cannot be assigned definitely to any

period, but appear to overlie the Upper Cambrian. The pitch is rather steeply to the west at both ends, and about level or pitching slightly to the east in places near the center of the tunnel. The strike is about 60° from the terminal axis. There are also many local irregularities and some faulting. None of the rock was timbered, except where broken up by faulting. Much of the tunnel that is in hard rock has slips, some of them clayey and talcy, which make the roof unsafe when weathered, and will require concreting. There was little water, owing to the fact that cracks which carried water formerly had become filled with quartz. The rock temperatures did not exceed 75 degrees. "Popping" was observed in the quartzite; that is, pieces of rock from the roof and sides, not shaken by blasting, would fly off with a loud report. This has always stopped after a few weeks exposure to the air.

Preliminary Work.

On the east side it was necessary to build 3 miles of temporary, heavy, side-hill railway to reach the camp site, and take out a rather heavy approach cut, before tunneling could be started. The approach cut was advanced sufficiently to start one wall-plate drift in January, and the other in February, 1914, the cut being finished in July.

On the west side about 1½ miles of temporary railway had to be built, and the same quantity of stream diversion, before the approach cut could be started. One 85-ton and one 100-ton shovel were worked both day and night in this approach cut, from December, 1913, until the finish, in June, 1914, when the tunnel drifts were started.

Camps.—The camps were built as soon as the track reached the respective sites, being finished about the end of 1913. They provided room for 500 men at each end, and were comfortable and sanitary. Hot and cold water, steam heat, sewerage, electric light, and good ventilation were provided.

Plant.—There was a power plant at each end, with five 150-h. p. boilers, equipped with special grates and induced draft, so that slack coal could be used for fuel. The boilers were run generally much beyond their nominal rating.

Each end had a capacity of about 4 000 cu. ft. of low-pressure air, that is, air at from 100 to 125 lb. at the compressor, with from 90 to 100 lb. at the drills, and a capacity of 1 500 cu. ft. of high-pressure air, that is, from 1 000 to 1 100 lb. pressure at the compressors, and

from 800 to 900 lb. pressure at the charging stations. Ingersoll-Rand compressors were used, two-stage for low and four-stage for high pressure, with inter-coolers. The steam ends were compound condensing. The compressed air passed through an efficient after-cooler, so that little trouble was caused by the freezing of moisture in the compressed air when exhausted by drills, pumps, and blowers. The plant was properly put in and properly looked after, and caused practically no delay.

Earth Section at East End.

There are 1 200 ft. of glacial drift at the east end of the tunnel. This material carries considerable water, due to seepage from the side of the mountain on one hand and Bear Creek on the other, the tunnel being below the creek level. The material was hard and compact when first opened, but ran when worked up or exposed to the air.

Wall-plate drifts (see Fig. 3) were started in January and February, 1914, as soon as the approach cut was down to the wall-plate grade, and finished to rock in July. From these drifts a stope was started in March, and segment timbers were placed for about 100 ft. Owing to a change of plan by the Railway Company, this segment timber had to be removed and rebuilt to a larger section, so that stoping and timbering ahead of this point could not be resumed until June. The timbering from the wall-plate up was completed in October. A locomotive crane was found very useful for taking the timber and other material from the framing yard and delivering it in the wall-plate drifts. After the wall-plate drifts met the main heading, in July, the material from the break-ups or stopes was hauled to the first cross-cut and out of the pioneer heading, so that it would not interfere with the timbering. Previous to that time it was dumped at the portal and reloaded by the steam shovel, together with the material of the approach cut. The material from the break-ups was passed down through a chute into the small tunnel cars. Considerable turning and crushing of the wall-plate occurred, necessitating a great deal of propping of the segments.

In August, the steam shovel, having finished the approach cut, started on the tunnel excavation, being operated by compressed air. During the day shift, the wall-plate was supported on temporary batter posts as the shovel progressed, and the night shift straightened the sides and set the plumb posts and lagging. During the night shift,

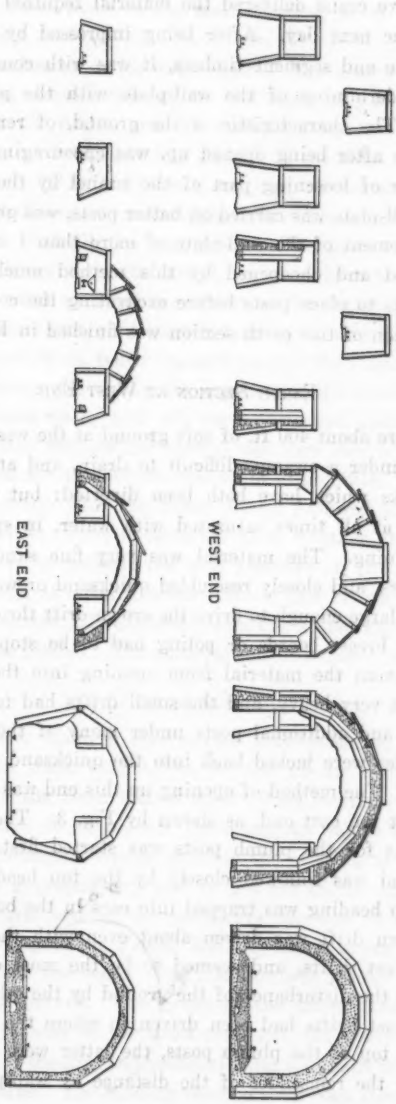

FIG. 3.

the locomotive crane delivered the material required for the segment timbering the next day. After being impressed by the crushing of the wall-plate and segment timbers, it was with considerable anxiety that the undermining of the wall-plate with the power shovel was attempted. The characteristic of the ground, of remaining firm for a short time after being opened up, was encouraging. As it turned out, the fear of loosening part of the tunnel by the side sliding in, while the wall-plate was carried on batter posts, was groundless. There was no settlement of the wall-plate of more than 1 in., and the work was hastened and cheapened by this method much more than by driving drifts to place posts before excavating the core of the tunnel. The excavation of this earth section was finished in December, 1914.

Earth Section at West End.

There were about 400 ft. of soft ground at the west end. The west portal was under a swamp, difficult to drain, and at the intersection of two creeks which have both been diverted; but this soft ground section was at all times saturated with water, in spite of efforts at surface draining. The material was very fine sand and clay, with large boulders, and closely resembled quicksand or wet concrete. One boulder was large enough to drive the crown drift through. The cracks between the breast boards or poling had to be stopped with hay in order to prevent the material from running into the heading. This material was very heavy, and the small drifts had to have sets about 2 ft. apart, and additional posts under many of the caps. Boulders near the sides were jacked back into the quicksand in order to clear the timbers. The method of opening up this end was entirely different from that at the east end, as shown by Fig. 3. The bottom heading of the drifts for the plumb posts was started first, with a view to drainage, and was followed closely by the top heading. The muck from the top heading was trapped into cars in the bottom heading.

The crown drift was driven about even with the top heading of the plumb-post drifts, and seemed to be the most difficult of all to hold, due to the disturbance of the ground by the other drifts. When the plumb-post drifts had been driven to where the rock reached the level of the top of the plumb posts, the latter were discontinued and replaced for the remainder of the distance by wall-plate drifts, from

which a cross-cut was made to the main heading when the full rock section was reached.

After the plumb-post drifts were finished, the plumb posts, being double 12 by 16-in. timbers, were all set and thoroughly blocked against the timbering in the drifts, and the wall-plate was set on the rock beyond the posts. A break-out was started in the sides of the crown drift, about 100 ft. from the portal, and the timber segments were put in, working both ways from this break-out. The muck from break-outs was used to back-fill the post drifts. The posts and segments were set leaning away from the portal, and iron bars were spiked on the segments in order to resist the thrust of the material toward the portal. Other break-outs were started farther in, and segments were set under the crown bars, trued up, and packed thoroughly by timber between the segments and the timber supports of the outside segments. No wall-plates were used, and the segments were generally 32 in. thick. Work in this soft ground section was very slow and expensive. The time required for the 400 ft. was from June, 1914, to February, 1915. The excavation with the power shovel followed the timbering operations. There was some uncertainty as to whether or not bracing would be necessary to prevent the side pressure on the plumb posts from shoving them in after the excavation had removed the earth resistance on the tunnel side of these posts; but no movement occurred, and no bracing was needed. The material sets or hardens when drained.

East Pioneer Heading.

The east pioneer heading was started in September, 1913, about 50 ft. north of the main tunnel, 700 ft. west of the east portal, and about 60 ft. above the main tunnel level. This location was adopted in order to save 700 ft. of pioneer tunneling, to reduce the quantity of soft ground heading, to enable work on the heading to start sooner than that on the approach cut, and to get rid of the muck readily. The power was furnished by the temporary erection of an old compressor along the Canadian Pacific Railway track above and a pipe line down the hill to the work. This heading was run as nearly level as drainage would permit. The grade of the main heading reached the grade of the pioneer at the third cross-cut, the two former cross-cuts being driven to the dip, and material from the main heading being hoisted up the incline. The heading reached solid rock about 600 ft. in,

at which point the first inclined cross-cut was started, at about the beginning of 1914. The pioneer tunnel, in rock, was driven about 2 miles in 1½ years. The maximum monthly progress was 776 ft. The daily average was 20 ft. for the entire drift in rock.

West Pioneer Tunnel.

The west pioneer heading was started by an incline, 300 ft. long, from the rock outcrop, 700 ft. east of the west portal, about 150 ft. above the main heading level, and 50 ft. south of the main tunnel line. This location was selected in order to provide dumping ground, shorten the length of heading to be driven, avoid soft ground tunneling, and permit an earlier beginning than by waiting for the approach cut excavation. This incline was very wet, and took 2 months to drive, being finished in the latter part of July, 1914. This pioneer tunnel was driven for a length of more than 1½ miles in less than a year, the maximum monthly progress being 932 ft., which is far beyond any previous American record known to the writer. The daily average of 24 ft. for nearly a year, largely through very hard quartzite, is also unusual.

Pioneer Headings in General.

The pioneer tunnel, in rock, was 7 ft. high and 8 ft. wide. It was driven with light hammer drills, using hollow steel, with water attachments. Three drills, in general, but four in the hardest rock, were used in a heading. Spare drill machines, for the replacement of drills out of order, were kept conveniently at hand in the heading. No repairs were made under ground. The hammer drills are convenient and rapid, the delay and expense of their constant breakage perhaps balancing the advantage of speed under ordinary conditions. The drills are mounted on a light horizontal bar, about 18 in. below the roof line. Air and water are taken over the muck pile, or on hooks in the side, by a single hose line for each, to a manifold from which short individual hose lines supply the drills.

Light cars (½ cu. yd.) were used for muck, and the latter was taken off the track, instead of building sidings for this purpose. Shoveling plates were used at the face and on the side away from the track for some distance back of the face, in order to facilitate the handling of empty muck cars. The ventilating pipe was a 12-in. wooden water pipe connected to the Connersville blowers used for the exhaust.

FIG. 4.—BEGINNING DRILLING FROM UPPER SET-UP OF BAR IN THE PIONEER HEADING.

FIG. 5.—MAIN HEADING, SHOWING ENLARGEMENT DRILLING.

This pipe was hung on the side away from the track, close up to the roof, and was carried to within 20 ft. of the face. Little damage was done to this pipe by blasting. The blowers were started exhausting when the first shot was fired, or a little before, and were run for 20 min. The men got back to work in from 5 to 10 min. No compressed air was allowed to be blown out for ventilating purposes. After a round was shot, the drillers followed the smoke back, barring down the roof, bringing explosives to re-shoot, and wetting down the muck pile, sides, roof, and face with water hose. The muckers cleared the track and began loading the muck which was scattered back.

When no further blasting was required, the lights were hung, the foreman sighted the line and grade point in the face, and the drilling gang set up the horizontal bar, placed their drills and proceeded. There was rarely any muck to be handled before the drilling could be started, as it was thrown back from the face by the heavy loading in the bottom holes and the fact that they were shot last, for this purpose. There were two helpers to three drills, and they brought up and changed the steel and adjusted the drill machines. When the drilling from the upper set-up was completed, the drillers took down the machines and carried them back, with the hose connections still attached, and oiled them up. After the mucking was done, the bar was dropped to the lower set-up, near the floor, and the drills were set to drill the bottom holes or lifters. The drills were carried forward, put on the bar, and were drilling sometimes in less than 2 min. after the bar was dropped. While the bottom holes were being drilled, the muckers laid the track, adjusted and covered the mucking sheets with muck, and brought up the explosives. The holes were loaded by the machine men, helpers, and foremen.

For the small part of the tunnel where re-shooting was not necessary, an 8-hour shift could do two rounds per shift, or a little better. Two men pick down the muck, and three men load the car and push it out, while three others stand by with an empty car, ready to put it on the track and load it. The three men taking out the loaded car return near the face with an empty car, take it off the track, and rest until the load comes out. The men get a rest from the monotony of steady continuous shoveling, and the empty car is available at once after the load goes back. The pipes for ventilating, and

for air and water were laid by a pipe man and helper, who looked after several headings.

Doing this work with muckers was unsatisfactory. Muck cars were taken from the heading back to a siding by a single mule, and from there to the dump by a two- or three-mule team driven tandem, until this method became inadequate, and then compressed-air locomotive haulage was substituted for the long haul. The heading muck cars, after the shovel and switching track had cleared a cross-cut, were taken to the cross-cut, pulled up an inclined trestle by air hoist and cable, and dumped into standard-gauge cars, as shown by Fig. 2. The cross-cuts are from 1 500 to 2 000 ft. apart, as shown by Fig. 6. Air pressure was maintained at about 90 lb. at the drills, which required 125 lb. at the compressors toward the end of the work.

The rounds were usually 6 ft. The cut holes were generally shot once or twice, and the remainder of the cut was shot with the rest of the round. All shooting in headings was done with fuse. The explosives used were 40 and 60%, low-freezing gelatine, with No. 8 caps. The rock was hard to break, and the quantity of explosives was necessarily high. From 21 to 28 holes were drilled in the pioneer face. Change of shifts was made at the heading, the shift coming on taking the tools out of the hands of the shift finishing. Three shifts a day were worked every day in the year, except for one day at the east end, due to the burning of the fan house, and one day due to the breaking of the air main by a snowslide. The pioneer gang drove the cross-cuts between the pioneer and the main tunnel heading. The pioneer tunnel was not driven for the last mile, connection being made by the main heading only, which was all drilled up for enlargement before the enlargement blasting reached this section. The main heading work had to be completed before the enlargement blasting and mucking reached the last cross-cut, as it would have been impossible to maintain the air connections, or ventilate the main heading, after that time, so as to allow continuous work.

Main Heading.

The main heading, generally known on the work as the "Center Heading", was entirely through the rock section. It was 11 ft. wide and 9 ft. high, the center line being the same as that of the com-

pleted tunnel and the bottom being 6 ft. above the sub-grade. The position and size were such that lateral holes could be drilled from this heading to break the enlargement to the required dimensions. The air, water, and ventilating pipes for this heading were branches from the mains laid in the pioneer heading. Access to this heading was obtained through the cross-cuts from the pioneer, and muck was handled around the enlargement operations by the pioneer route. This heading was generally driven in a westward direction, on account of the drainage. The system of driving was similar to that in the pioneer. The rounds averaged about 7 ft., and 32 holes were drilled in the hardest rock. The main heading was sometimes driven from several faces. The progress is shown by Fig. 6. The average daily progress per heading at the east end was slightly more than 16 ft., and the maximum monthly progress was 621 ft. The average daily progress per heading at the west end was 20 ft.; the maximum monthly progress was 762 ft.

Headings in General.

The headings were sublet at a price per foot and a bonus for more than 450 ft. per month, the sub-contractor furnishing the labor and explosives only. This arrangement proved unsatisfactory, and was discontinued in September, 1914. After this time a substantial bonus, based on the monthly footage and equated for hard rock, was given, and divided among all men directly connected with the heading driving, in proportion to their regular wages earned for the month. It was agreed that the rate of bonus would not be reduced. The latter arrangement resulted in 23% greater speed, and a large saving in compressed air and other items furnished to the sub-contractor under the former arrangement.

Enlargement.

Drilling.—The enlargement drilling, after some experimenting, was done as shown by Figs. 2 and 7. Each hole was pointed by clinometer, the column carrying the drill being set always at the same distance off the center line, and the arm for the lower and upper sets being always the same distance above the sub-grade. Line and levels were furnished by the Railway Company's engineers, and a string was stretched by which the columns and arms were located. Each drill hole had its proper distance from the arm. The drill

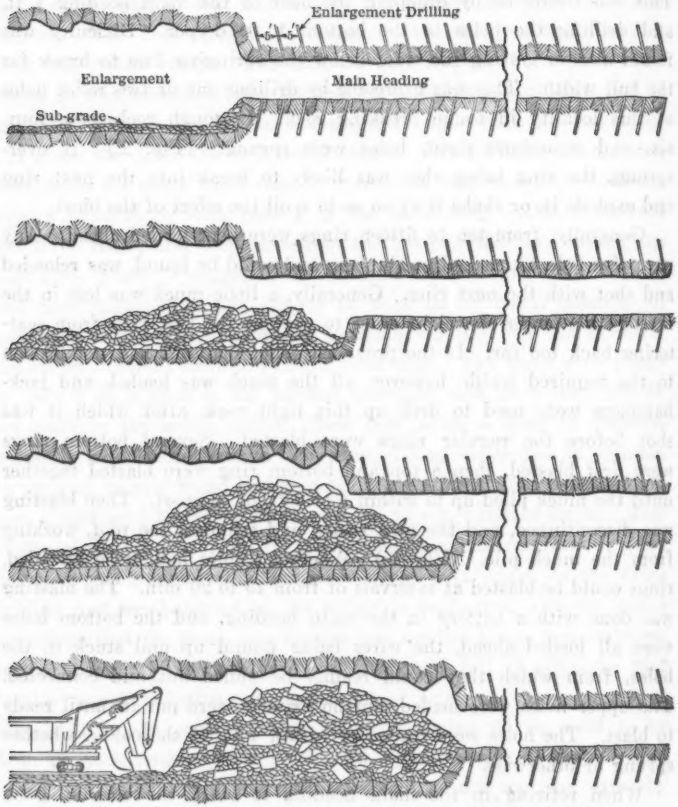
holes were thus bottomed at a regular distance beyond the neat line of the completed excavation. The holes, being bottomed with reference to the line and grades given by the engineers, were not affected by irregularities in the heading driving. The columns were set by men for that purpose, so that the drillers and helpers had only to do the drilling. The drill steel was brought to the drillers, and the dull steel was taken away. The drillers and helpers were paid their wages in any event, but the footage for each man was kept, and if the price set per foot drilled amounted to more than his wages, he was given the difference as a bonus check. Air and water connections were made for every third ring of holes, and only one drill machine, though handled by each runner of the three daily shifts, completed the three rings, and then moved to the head of the line, taking the next three rings. Congestion of men and material was thus avoided, and each man had a fair chance to work on an equal quantity of hard and soft rock. There was extreme variation in the quantity drilled by different men and in different rock. The same man might do only 6 ft. a shift in the hardest quartzite, and more than 100 ft. per shift in the softer schist. New men, after a month's practice, generally made more footage than men of long experience in mining. In general, it was found better to train green men than to try to get men accustomed to piston drills to learn to run hammer drills. Most of the rings were 6 or 6½ ft. apart. When explosives rose in price it was found economical to space the rings 5 ft. apart, as the extra drilling cost was balanced by the saving in explosives, with the added advantage that the muck was broken into smaller pieces and scattered farther back. Where the roof was soft and full of slips, so that trouble was anticipated, the upper set of arms on the column was lowered 1 ft., in order to leave some trimming of the roof to be done by jack-hammer, flat holes, and light blasting. The air and water for the enlargement drilling, as well as the supplies, came by the pioneer tunnel and the cross-cuts, so that this drilling was not disturbed by the enlargement blasting. The drilling for the last mile, where no pioneer tunnel was driven, was started at the middle and progressed toward the portal, the track, pipe, etc., being removed as the drilling was finished. The stopping of the pioneer tunnel was well-timed, as the main heading was driven and the enlargement

drilling completed just in time to avoid delaying the enlargement blasting and mucking at the east end.



Enlargement Blasting.—There was considerable difficulty in breaking the bottom to sub-grade when the rock excavation was first started. This was overcome by dropping the floor of the main heading 1 ft. and drilling the holes in the bottom 1 ft. deeper. Difficulty was found also in getting the sides below the springing line to break for the full width. This was overcome by drilling one or two relief holes at this locality in tough breaking rock. In tough rock, two, four, six, and sometimes eight, holes were sprung. (Fig. 2.) If oversprung, the ring being shot was likely to break into the next ring and explode it, or shake it up so as to spoil the effect of the blast.

Generally, from ten to fifteen rings were kept loaded ahead. Any part of a hole which had not broken, and could be found, was reloaded and shot with the next ring. Generally, a little muck was left in the face by the power shovel in order to prevent the first ring from scattering back too far. If the previously shot material had not broken to the required width, however, all the muck was loaded, and jackhammers were used to drill up this tight rock, after which it was shot before the regular rings were blasted. Several bottom rings were first blasted, then a top and bottom ring were blasted together until the muck piled up to within 4 or 5 ft. of the roof. Then blasting was discontinued, and the men scaled and trimmed the roof, working from the muck pile. (Fig. 8.) Where no holes had to be reloaded, rings could be blasted at intervals of from 15 to 20 min. The blasting was done with a battery in the main heading, and the bottom holes were all loaded ahead, the wires being wound up and stuck in the holes, from which they could readily be pulled out and connected. The upper holes were loaded, but no primers were put in until ready to blast. The holes were loaded to within 4 ft. of the collar, whether sprung or otherwise.

When retiring in the main heading to blast, the blasting gang took back the scaling tools, so that they might examine and scale the roof of the heading if necessary as they returned. After several rings had been blasted, the power shovel crew commenced to clean up the beginning of the muck heap, and only retired a few minutes for the following blasts. Several top rings were generally held and shot at meal times, when the shovel had excavated sufficient muck to

provide room for more without blocking the airway and manway over the pile.

The smoke and gas from the blasting were quickly taken out by the fresh air forced into the pioneer tunnel by a "Sirocco fan" at the

LONGITUDINAL SECTION, SHOWING ENLARGEMENT BLASTING

FIG. 8.

portal. The air circulated through the pioneer tunnel and the cross-cut ahead of the blasting, and then back through the main heading, over the muck pile, and out at the portal of the main tunnel. This circulation was prevented from short circuiting by stoppings and doors in the

cross-cuts passed by the shovel. The quantity possible to shoot depended on the distance the muck was thrown back, or the quantity of muck for which there was room without interfering with the scaling and trimming of the roof; it varied from 24 to 110 ft. Much time was lost in taking up the track before blasting, in cleaning up the thinly scattered muck directly after a blast, and by other delays incidental to each clean up, which made it desirable to shoot as many rings as possible.

Enlargement Mucking.—Mucking was done with small steam shovels, with cylinders enlarged so as to be efficient at 100 lb. air pressure, and with the boom sheaves set back so as to shorten the booms and protect the sheaves. The shovels loaded the muck into 12-yd., standard-gauge, air-dump cars. The cars were shifted to the shovel by two small compressed-air locomotives, and were taken from a spur near the shovel to the portal by a larger compressed-air locomotive; they were taken by a steam locomotive from the portal to the dump. During the past year the shovels mucked 18 550 ft. throughout 3½ miles of tunnel, or more than 2 ft. per hour. Blasting and trimming took about one-quarter of the time. The best monthly run for one shovel was 946 ft. at the east end, and 1 030 ft. at the west end. The ground between the third and fourth cross-cuts at the west end became so dangerous, owing to the material in the roof and sides falling, that one shift out of three had to be devoted to scaling this section until it was concreted. About 2 500 cu. yd. fell or was scaled in this section, on account of the disintegration of the material on exposure to the air. The scaling car throughout the work was handled by the air locomotive, and the scaling was done by the shovel crew or others during the time the shovel was stopped for enlargement blasting. Any rock not broken to the required dimensions was drilled off the muck pile, or from the floor, as the shovel cleaned up as far as possible, or from a car left at the shovel crew's meal time, and shot before the next rings were blasted. The enlargement drill holes were the general guide as to the trimming required, such points as were missed being marked by the Railway Company's engineer. There was very little over-breakage.

Concreting.

About 1½ miles of the tunnel, including the soft ground at each end, required concreting. This work was sublet to the Bates and

Rogers Construction Company, of Chicago and Spokane. The concrete section is heavily reinforced, which prevented the use of the pneumatic method of placing. The sub-contractors used wooden forms, and deposited the concrete from a platform near the roof reached by an inclined trestle. The concrete mixer was on a car, and the materials were on other cars back of it. The concrete from the mixer flowed into a small car which was hauled by cable up the trestle incline to the high platform, from which it was shoveled into the forms. Much of the lining required back as well as front forms, and the space behind the back forms was filled with rock or wood. This back-form and back-filling work was slow and expensive, especially where there were only a few inches between the back forms and the rock. The concreting has been well done, but the work is behind time, owing largely to conditions which the sub-contractors could not control.

General Results.

The tunnel has been finished 11 months ahead of the contract time, and for a substantial sum less than the price bid. There have been no strikes, or interruptions of the work. The management has had the necessary money and authority, and has been given a free hand, both by the Railway Company and the contractors, and has had the loyal support and valued assistance of the men, notably Messrs. J. Fowler, Assistant Superintendent, T. Truran, Master Mechanic, J. Roberts, Chief of Office Force, and M. C. Brian, Shovel Runner.

Engineering.

The Railway Company did the necessary engineering work. Messrs. F. F. Busteed, H. G. Barber, and W. A. James, M. Am. Soc. C. E., were successively in charge, Mr. J. G. Sullivan being Chief Engineer.

DISCUSSION

Mr. Lauchli.

E. LAUCHLI,* ESQ.—Those who have followed closely the progress made in driving Rogers Pass Tunnel cannot but admire the skill displayed by the engineers and contractors connected with this great enterprise; and, no doubt, the completion of this bore will give a greater impulse to work of this character in America.

The speaker, who was retained in an advisory capacity by one of the contractors bidding on this work, was well aware of the conditions preceding the driving of this tunnel. In his opinion, bidding on this work was a gambling proposition without precedent, owing to the fact that the railway company did not provide the bidders with sufficient information relating to the geological formation of the range to be tunneled. The accuracy of this statement is backed by the fact that, according to Mr. J. G. Sullivan, Chief Engineer of the Canadian Pacific Railway, expert tunnel contractors bid on this work from $8 to $11.25 per cu. yd. for excavation—prices hitherto unheard of in connection with double-track tunnel excavation.

That the driving of this tunnel has been a success will not be denied by the Profession, but, in the speaker's opinion, the results attained are due more to the unusually favorable conditions—as far as material penetrated, absence of rock pressure, small quantity of water underground, and low rock temperatures are concerned—than to the driving methods adopted by the contractors.

In preparing their bids, those interested in this work, had to assume that there would be a reasonable amount of difficulty, and this, no doubt, accounts for their selection of the bottom-heading method of tunneling, the only method known to-day, which insures absolute success, both under favorable and unfavorable conditions. Now, as just mentioned, there was no information available of a nature to cause bidders to select a driving method, practicable under ideal conditions only, and no experienced tunnel contractor could afford to gamble on an undertaking of this magnitude.

The driving method actually adopted based its greatest expectations on the enlargement of the tunnel, and necessitated an auxiliary or pioneer tunnel. Ventilation alone did not call for an exceptional ventilation system, as has been proved during past years, in connection with the driving of tunnels from 5 to 9 miles long, driven under far less favorable conditions than those at Rogers Pass.

Had an intense ground pressure developed over a long section, or over several short sections, then in order to keep within the schedule of progress, the method of enlarging the bore at one point only would have necessitated such radical changes as to jeopardize the success of the enterprise. In Rogers Pass Tunnel it was possible to enlarge

* New York City.

Mr. Lauchli.

the tunnel at one point only, and an obstacle, such as intense ground pressure at the enlargement point, would have necessitated keeping the timbering, and probably also the masonry lining, close to the enlargement; and thus the blasting and mucking operations would have been greatly hampered.

On the other hand, the method of enlarging the bore to full section from several working points, as used for instance in the Loetschberg, Hauenstein, and Grangs Tunnels, in Switzerland, possesses the advantage of being adaptable both in light and heavy ground, and, under favorable conditions, such as met in Rogers Pass Tunnel, the drilling and blasting operations are at least as economical as those used in the last bore referred to, the only differences being the temporary heading timbering and the removal of the two side benches adjacent to the heading.

It may be useless to point out here that the removal of the benches could have been done with air-operated shovels. It is questionable, also, whether the total cost of driving this tunnel by the method actually adopted was less than it would have been by using the bottom-heading method. In the first place, the pioneer or auxiliary tunnel method involves practically two headings instead of only one, as used in connection with the European method; for, in this case, the length of the pioneer tunnel, together with the cross-cuts, is a little more than 20 000 ft., and, of course, this auxiliary tunnel is chargeable to the main bore. Then, also, it is questionable whether the weathering or ground pressure will not incur maintenance charges in connection with the pioneer tunnel and the cross-cuts, in order to avoid disturbances of the rock surrounding the main bore. The practice, also, of not lining the main bore at the very outset is open to criticism, as it is always desirable to prevent initial disturbances from taking place in the overlying strata, especially in deeply overlaid tunnels, rather than to check these later, perhaps under operating conditions in the tunnel.

The speaker, who made a careful study of the proposition, figured that, on the assumption of a daily progress of 20 ft. from each portal, and assuming that one-third of the tunnel would necessitate temporary timbering, also that the masonry lining would follow close to the excavation, the cost of driving this bore, with a bottom heading, would be $5 per cu. yd., exclusive of contractor's profit. Mr. J. G. Sullivan has stated* that the cost of driving the tunnel through rock, including the cost of driving the pioneer tunnel and the cross-cuts, "will amount to a little less than $5 per cu. yd. for excavation in the tunnel proper."

In comparing the costs of different methods, the mistake has often been made of comparing short tunnels with long ones, such as the

* *Engineering News*, February 24th, 1916.

Simplon or the Loetschberg; for, it is a well-known fact, that the cost per linear foot of long tunnels is higher than that of short ones. For instance: for the first kilometer of the Loetschberg Tunnel, the cost was $160 per lin. ft. including lining; the cost for the seventh kilometer (center of tunnel) was $224 per lin. ft., the average for the whole bore being $201.65 per lin. ft. Mr. Lauchli.

On the other hand, the cost of Rogers Pass Tunnel can be compared favorably with that of the more recently completed Hauenstein Tunnel, 26 680 ft. long, driven under conditions very similar to those encountered in Rogers Pass Tunnel, although less favorable. The wages paid in connection with the Hauenstein Tunnel were higher than in the case of the Loetschberg Tunnel, being about half as much as those paid at Rogers Pass Tunnel.

On the other hand, the tunnel was driven 20 000 ft. from the south portal, the remaining 6 680 ft. being driven from the north portal, and this alone increased the cost. Another feature of material importance is the fact that the bore was lined throughout, the masonry lining being kept close to the excavation. This feature also complicates driving operations, and increases the cost of excavation by about 50 cents per cu. yd.

Finally, the mining operations had to be carried on very carefully on account of swelling ground, and at several points masonry inverts had to be provided; yet the cost of excavation was less than $2.70 per cu. yd. Had it been possible to line this tunnel after the completion of the excavation, and, also, had the tunnel been taken out equally from each end, there is no doubt that the cost for excavation would not have been more than $2.25 per cu. yd.

This bore was driven at an average speed of 750 ft. per month for the heading, for a whole year (maximum 1 030 ft.), and at the rate of 658 ft. per month for stoping (maximum 870 ft.), also at a rate of 656 ft. per month for enlarging to full section (maximum 850 ft.); and the masonry lining was carried on at the rate of 650 ft. per month.

Robert A. Shailer,* M. Am. Soc. C. E.—The speaker is of the opinion that the pioneer heading, entirely outside the main tunnel section, is a new feature in tunnel construction. Mr. Shailer.

Apparently, the time of completion was vital, and the fact that the contract was completed more than 11 months ahead of the specified time surely shows that the adoption of the pioneer heading was justified economically.

To the advantages which Mr. Dennis claims for this heading there might be added: that it enabled the work on the long rock tunnel to be well under way before the earth and soft ground approaches on the

* New York City.

Mr. Shaller.

east and west ends were commenced; also, that the pioneer heading served the purpose of a pilot tunnel to inform the contractor as to the character of the rock through which the main tunnel was to be driven.

Had the speaker's opinion been asked as to the plant layout before the work was commenced, he would have said that five boilers, each of 150 h. p., would prove inadequate to fulfill the requirements at each end of the tunnel, namely: 4 000 ft. of free air compressed to 100 to 125 lb., and 1 500 ft. of free air compressed to 1 000 to 1 100 lb., as well as power for the lighting, ventilating, and pumping plants; and apparently, that opinion would have been—in some degree, at least—correct, for, the author says: "The boilers were run generally much beyond their nominal rating", and this, as all know, is not good for the boilers or for the contractor's pocketbook.

It is noted that there was a drop of approximately 15% from the power-house pressure to the drills, and of 25% to the high-pressure charging station, due probably to the pipe lines being of too small diameter. This loss seems excessive, and must have proved expensive.

The descriptions of the various tunnel operations are clear and concise, and the speaker thinks the members of the Society are indebted to Mr. Dennis for this paper.

Mr. Keays.

R. H. KEAYS,* ASSOC. M. AM. SOC. C. E. (by letter).—This is a very interesting paper, as it explains new methods for obtaining speed in driving long tunnels in rock.

Some years ago it was generally stated that the art of tunnel driving in Europe was much further advanced than in America, as was shown by the great progress in the various tunnels through the Alps as compared with America's much more modest attainments. The proper reply was to argue that the reason American engineers did not specialize in speed was that they had no long tunnels to drive, and when, for financial reasons, they found it necessary to speed up their work they would soon find a way to do so. Certainly, some of their records of late years have been very creditable.

In the writer's opinion, a large part of the credit for the great progress should be given to the improved types of drills developed during the last few years. Where it used to be agreed that the controlling feature of speed was the time taken to drill the heading, it is now considered that tunnel driving is a mucking proposition, and the feature to which most attention should be devoted is the cleaning away of the muck.

In explaining why the pioneer tunnel method was used for the Rogers Pass Tunnel, the author states that the usual "top heading and

* Jersey City, N. J.

bench" method was considered too slow and the "bottom heading" method too expensive. Mr. Keays.

As to the "top heading and bench" method, the writer is of the impression that it has not yet shown its capabilities as to speed, no tunnel driving with modern drills having as yet been attempted where speed was the primary object and where the conditions were so nearly ideal for fast work as in the Rogers Pass Tunnel. The writer has never used the bottom heading method, but has always heard it recommended for its economy. Substantiating this claim, the writer knows of several tunnels where it was used, but they were of such short length that speed was of minor importance.

From a careful reading of the paper, the writer is of the opinion that the author has not demonstrated that the pioneer heading has enough advantages to justify its use as a standard method.

The author gives a list of reasons for using the pioneer heading, showing various advantages which no doubt would expedite work in the main tunnel; but, in the writer's opinion, it would be very little. The paragraphs explaining the location of the portals of the pioneer headings, however, would indicate that, on account of avoiding a lot of soft ground work, the pioneer heading could be driven far in advance of the main heading, but as no heading was driven in the main tunnel, using the pioneer heading to work from, the writer does not understand how greater speed was made in the main tunnel on this account. It merely cheapened the cost of driving the pioneer heading and provided better dumping ground.

The writer assumes that the main heading was being excavated at one face only at any one time, and also that enlargement operations were being carried on at one place only.

Of the reasons given by the author for adopting the pioneer heading, No. 2 is the only one that could tend to expedite work in the main tunnel. Reason No. 1, treating of ventilation, should have no influence on the speed, as the matter of ventilation at the working face can be taken care of very well in the "top heading and bench" method, and ventilation between the heading and portal is not important.

No. 3, of course, would not be an advantage in the "top heading and bench method", for the enlargement operations would be close to the heading.

No. 4 could hardly be called an advantage, for the rate of speed depends on the enlargement operations.

No. 5 is rather unimportant.

No. 6 would also be of no advantage, as the enlargement operations are close to the heading.

Ventilating systems, as usually put in, are disappointing. There is no agreement as to the relative advantages of the pressure and suc-

Mr. Keays.

tion systems, the size of pipe to be used, the pressures, or the quantity of air necessary.

It may be said that much larger pipes are required with suction than with pressure systems in order to handle the same quantity of air. The suction system keeps the air of the whole tunnel in relatively good condition, but, at the heading itself, where the men are working, it has the least effect. This trouble is augmented, generally, by the fact that the pipe used is of very light weight and is leaky at the joints, so that there may be very little air taken in at the end.

The pressure system, on the other hand, clears out the heading first, so that the men can go back to work immediately, and ventilation between the working face and the portal is not important.

The pressures generated at the fan are usually so low that a very large pipe is needed in order to get the volume. For economical reasons, a large pipe is always made of light material, which is not satisfactory.

The writer, therefore, on account of the foregoing considerations, believes that a medium pressure system, using a relatively small, screw-joint, standard steel pipe for delivering air to the heading, is the best.

On a recent job he used a Connersville blower, good for a pressure of 10 lb., delivering 750 ft. of air per min. to a heading somewhat more than a mile distant. The pipe was of steel, 6 in. in diameter, and the maximum pressure was about 7 lb. The condition of the air at the heading was always good. The heading and bench were always shot at the same time, every 8 hours, and the blower was usually run for about 2 hours each time.

Mr. Lavis.

F. Lavis,* M. Am. Soc. C. E. (by letter).—This account of the most successful tunneling operation in North America—and this is said with, it is believed, due appreciation of all the work of this kind which has been done in recent years—is a tribute to the advent of the engineer as a director of a type of construction which requires the planning and organizing ability of which usually only the trained engineer is capable.

Confronted with the problems of organization required for the successful economical completion of the long Alpine tunnels, Europeans long ago realized that these were problems for the engineer, and were not of the kind which could be put through solely by "pick, shovel, and pluck," or mere driving power, unaided by a trained mind to plan and execute.

The writer fully recognizes the value of the qualities of the contractor, especially those of the railway contractor, which are very necessary, and which engineers seldom possess. The need of planning,

* New York City.

of co-ordinating the work of the organization with the plans, the successful modification of the plans to fit both the conditions and the organization as they develop, are, however, essentially qualifications which the properly trained engineer alone possesses. Mr. Lavis.

Though this is not the first tunnel driven in North America which has demonstrated the ability of the engineer as an organizer along lines which require this necessary co-ordination of planning with execution, it is the latest and most successful, and the writer believes that the realization of this phase, of the conduct of the operations which have resulted so successfully, is of quite as great importance as the recognition of the successful application and improvement in the "pioneer heading" method, important as this latter is as a demonstration of efficiency.

There is little opportunity for comment in regard to the methods used. Figures are not given, though it is hoped they may be supplied later, either by the author or by the officials of the railroad company, showing the value of the time saved and the economy of the extra expense involved in the speed of driving. The writer has no doubt the expense was justified, but the author's comments would be of great value, if he would indicate his views on the economical speed from the standpoint of construction alone without regard to operating losses to the railway, and on the value of the saving to the railroad company.

There is a growing tendency to give, in connection with the description of works of this kind, either exact or approximate costs, and it is rather to be regretted that they have not been stated in this case, as such information has a distinct value, and its suppression is of doubtful utility to the railroad company or the contractors.

The paper is filled with instances which show the careful continuous study of conditions and improvements in details as the work progressed. Many of these latter are not altogether new; some of them have been advocated by the writer and others; but as their general application to tunneling is by no means common, even yet, it seems permissible, even at the risk of repetition, to refer briefly to some of them:

Ventilation is a *sine qua non.*
Bonus system used.
Hammer drills used entirely, columns carefully set with relation to line and grade, holes pointed by clinometer.
Three helpers were used for each two drills.
Fuse was used instead of batteries for blasting.
Water was used to wet down the muck pile and wash the dirt from the sides, roof, and face.
Muckers have brief rest between each carload.
Mucking sheets were used.

Mr. Lavis. There is also one statement full of significance to those who have had much tunnel experience, namely, that "The plant was properly put in and properly looked after, and caused practically no delay". This epitomizes the attitude of those responsible for the conduct of the work, and indicates one of the most important reasons for the success attained.

Mr. Sanborn. JAMES F. SANBORN,* ASSOC. M. AM. SOC. C. E.—The speaker has been asked to call attention to a volume, now being prepared regarding the tunnels of the Catskill Aqueduct, recently completed. Dr. Charles P. Berkey, of Columbia University, the Geologist of the Board of Water Supply, is undertaking to collect, as far as possible, information for a comprehensive history of the geological features which had an important bearing on the tunnel design and construction of the several long siphons and other structures of the Catskill Aqueduct.

It is hoped that this volume will bring out some of the finer points of tunneling. Usually, a tunnel is driven, and one never hears anything more about it, unless, like Mr. Dennis, somebody has the courage to describe it in a paper.

Mr. White. LAZARUS WHITE,* ASSOC. M. AM. SOC. C. E.—The speaker visited Rogers Pass Tunnel in September, 1915, when it was being driven at about its most rapid rate. The profile (Fig. 1), shows that the mountains are only 9 000 ft. high, but, to the speaker, they looked as though they might be 19 000 ft. It was raining at the time; the mountains were covered with snow and ice; and there was snow in the woods; but the tunnel was dry. The work had then been advanced more than 2 miles from the west end and there was just a little trickle of water coming out of the entrance.

The rock was "made to order". It was one solid block, as far as could be seen, practically without faults or the disturbances usually found in rock, and, to the speaker's unpracticed eye, it appeared to be a hard shale or slate. He would hardly classify it as a hard quartzite, as Mr. Dennis does; but he probably knows.

The pioneer heading method appeared to be a very good one for that place, and the whole scheme of the tunnel and its execution a very good piece of work. In the speaker's opinion, it was the first successful combination of the Swiss and the American methods of tunneling. Other attempts have been made to combine the two systems, but they have not been successful, either financially or otherwise. This project, however, was successful in all respects.

The pioneer tunnel was of quite a small bore, and, as Mr. Dennis has stated, it served primarily for ventilation, because through it any quantity of air was sent around the heading, and blew out the smoke. The tunnel was both the driest and the best ventilated of

* New York City.

any the speaker has visited. On account of the extensive blasting that was done, it must be realized that the ventilation had to be well nigh perfect, because from fifteen to twenty rounds were set off in succession in order to break up the rock ahead of the steam shovel. Mr. White.

In any ordinary method of tunnel ventilation, this would have made the work difficult, if not impracticable, but, with this pioneer tunnel, the air was sent around and blown through the main tunnel. There was an immense fan in the pioneer heading through which there was always a strong wind blowing.

The most original part of the pioneer heading has a strong resemblance to the double tunnel of the Simplon. The main heading was more of a center heading than a bottom heading, and, by working within it, the men had plenty of time to do their drilling in the face, which previously had always limited the progress. In this case it did not; the blasting was done as rapidly as the shovel could take the muck. That shovel, of about 40 tons capacity, was worked just as hard as any shovel in the open. It loaded full-sized, 12-yd. cars, and there was continuous and very good service rendered to the shovel, with no interruption.

The speaker believes this progress could not have been made if the rock had not been so exceptionally good, because timbering would have delayed the work, and probably the method would not have been successful if much timbering had been required. Eventually, it will be necessary to concrete more of this tunnel than has yet been done, because the rock may weather.

Another feature, not brought out very strongly in the paper, which contributed very largely to the success of this tunnel, was the drills used. The speaker believes they were little water-fed drills. With these it was possible to maintain the high rate of progress in the heading, and they contributed very largely to the success of the work.

The camp was very well kept, but the speaker was surprised to note that the power plant was of such small capacity. The working organization was very effective, and, without intermission, sustained the undoubted record-breaking progress with which this tunnel must be credited. This organization, the speaker is informed, was brought from the United States, where the men had done some very rapid work on the Gunnison and Laramie-Poudre Tunnels.

The wooden water pipe, used for ventilation, served its purpose well, and was much superior to the ordinary iron pipe. It was well laid, and the joints were so tight that the exhaust could be conducted through it.

T. Kennard Thomson,* M. Am. Soc. C. E.—Mr. Dennis deserves the thanks of the Society for his very interesting paper, but it is to be hoped that he will add many details before its final publication. Mr. Thomson.

* New York City.

Mr. Thomson.

The speaker understands that the report of the late Virgil G. Bogue, M. Am. Soc. C. E., is a masterpiece of one of the foremost of old-time railroad engineers, and it would seem that its publication in full, in connection with this paper, would be of great value to other engineers and students. For that reason it is hoped that the author will prevail on the Canadian Pacific Railway Company to allow its publication in full.

Mr. Dennis' paper is of special interest to the speaker because he was engaged on the location and construction of the Canadian Pacific Railway from Medicine Hat to the west slope of the Selkirks in 1883-84-85. Haste, the key-note then, as it seems to be still, resulted once in a record for rapid construction, when 93 miles of railroad from Medicine Hat was built in 23 working days of June, 1883. This work, which included grading, bridges, culverts, and track-laying, but not very much ballasting, really made a marvelous record, considering the fact that all the supplies had to pass through Winnipeg and then be carried some 600 miles over a new, single-track railroad.

In those days no one ever thought that that railroad would ever be a financial success; it was considered merely as a political necessity, as the Dominion Government, at the time of the Confederation in 1867, had assumed the obligation of making physical connections between the separated provinces. Even the late Commodore Vanderbilt had so little confidence in it that he got rid of his holdings.

As a matter of fact, in those days, British Columbia was closer, commercially, to the United States than it was to the rest of the Dominion; and, even in 1885, the speaker found that Ontario or Quebec banknotes were not welcomed in British Columbia and were accepted only at a discount, while United States notes were accepted at par. This was partly due to the fact that in those days the face value of a Canadian banknote was not guaranteed by the Government as it is now. At present, however, the Canadian banking system is superior in many respects to that in the United States where a national bank in a small town has only the credit of its small capital back of it, whereas the smallest branch of some dozen strong Canadian banks has its powerful system behind it. Very few Canadian towns are not amply provided with such branches.

One reason for haste in those days was to get some return on the money as soon as possible, and an even more important reason was the fear that, if the road was not quickly completed, a turn of the political wheel might prevent it from being finished for many years.

In addition to the commercial reasons for haste in constructing the Rogers Pass Tunnel, the fear of snow slides may have been another incentive—the author has stated that the snowfall there is from 30 to 50 ft. a year. The speaker assisted in the design of the

first snowsheds on this road. These were to be constructed in cuts on the hillsides in such a way that the snow slides or avalanches would never strike directly on the roof of the shed, but merely shoot or slide over it. Some of these designs were modified by others, so that the roofs projected up too far, with disastrous results in every case. Trees adjacent to a snow slide would often be cut off as if by a knife about 20 ft. above the ground, or at the surface of the standing snow, by the force of the wind generated by the falling avalanche. Nothing can be built to stop those giant snow slides after they have fallen from 3 000 to 5 000 ft. The snow and ice piled up in winter many feet, and even after the intense heat of August a depth of some 30 ft. or more would be left. Mr. Thomson.

Would it not be appropriate for the author to insert a brief sketch of the life of Major Rogers, one of the most unique characters of a past age of remarkable engineers? He saved the Canadian Pacific Railway from following the Columbia River some 200 miles around—north and then south—by discovering the Rogers Pass which led due west, crossing the Columbia River twice.

The exceedingly favorable geological conditions encountered in this tunnel were not often found in the earlier tunnels in the Selkirks, one of which—a mud tunnel—was nearly completed when it was found that the two headings did not meet by 18 in. This was first blamed on the engineer, but after the lining had been ripped out and replaced, the tunnel at once collapsed. It was re-opened a third time, and again collapsed, after which it was abandoned, and the railway was run around the bluff on a 23° curve. It was operated on this curve for more than 20 years, and then a new tunnel was built much farther from the face of the bluff, where firmer ground was encountered.

In those days some of the grades were as high as 4½%, and negotiating them gave the engines so much trouble that safety switches were generally placed at the foot of the grade, so that if the train ran away it would have to take the switch, which had such a sharp grade uphill that the momentum of the train would rapidly be reduced.

The plan and profile, Fig. 1, shows how the original location wound around the hillsides in order to avoid more excessive grades, and permitting as rapid and cheap construction as possible. The profile also shows why vertical shafts could not be considered, as the hills stand as high as 5 000 ft. above the tunnel.

FRANCIS LEE STUART,* M. AM. SOC. C. E.—The speaker has read this paper with interest, as the rate of progress was strikingly rapid. As far as the speaker knows, a pioneer tunnel, similar to that used at Rogers Pass, has never been built in the East, although this method is in constant use in coal and iron mines. Usually, the tunnels in Mr. Stuart.

* New York City.

Mr. Stuart.

the East have not been so long, have had less cover, and construction progress has been expedited by shafts. The speaker has found it very difficult to compare the progress in tunnels—every one seems to have different conditions which affect the rate of building—in fact, even parts of the same tunnel are not comparable. In groping after a greater speed, a number of new methods have been tried.

In the Stuart Tunnel, one of the most recent built under the speaker's direction, at the Magnolia Cut-Off, on the Baltimore and Ohio Railroad, the tunnel section used was large, being 31 ft. in the clear horizontally, with side-walls plumb to 11 ft. above sub-grade, and a semicircular arch with 15½ ft. radius, giving a clear height of 22 ft. 11¼ in. at the center of each track.

To expedite matters, the contractor, H. S. Kerbaugh, Incorporated, put in a Marion 28 (⅝-yd.), dipper, air-operated shovel with which he widened the heading, which originally had an area of about 120 sq. ft., and took the bench to an elevation 6 ft. below that of the wall-plate, leaving 11 ft. in bench instead of the usual 17 ft. It effected a very considerable saving in time and expense, as it was possible to widen and place the steel segment at a rate of from 60 to 70 lin. ft. of arch section per week, as compared approximately with 45 ft. by hand, and to enable the remainder of the bench to be drilled without cat-holes. The speaker thinks that matters were about even, as to cost, and, with a little better roof, it should have been cheaper than the old method.

In a further effort to increase the rate of progress in the tunnel, it was decided to use Blaw steel segments to support the roof, in place of the usual timber segments. These consisted of two 7-in., 14¾-lb. channels, riveted together with two ¾-in. rivets, 2½ in. long, with 6¾-in. fillers between, at intervals of about 3½ ft. These segments were divided into three parts; the central portion was 18 ft. 3⅞ in. long, curved to a radius of 17 ft. 6 in.; the end portions were 11 ft. 3⅝ in. long, 5 ft. 0½ in. being curved to a radius of 17 ft. 6 in., and the remainder being a tangent to connect with a flanged foot resting on the wall-plate.

The three sections were connected with 9 by ¾-in. plates, 1 ft. 9 in. long, and with ¾-in. fillers. They were used in 2 015 ft. of this tunnel, or for 60% of its length, and, for the most part, were 5 ft. from center to center; otherwise they were 7 ft. 6 in. from center to center, depending on the character of the roof. All were tied together longitudinally with ¾-in. tie-rods 7 ft. from center to center. The lagging was placed directly on these segments, and was fastened through $\frac{9}{16}$-in. holes in the flanges. The sections were assembled in the tunnel and raised to position.

The use of these steel segments enabled the driving to be done more rapidly, as the cross-sections decreased an average of about 2 cu. yd. per lin. ft., and, as the segments came entirely within the section of

the concrete lining, there was an additional saving of practically 2 cu. yd. of concrete per cu. ft. Mr. Stuart.

The speaker's conclusion was that speed was made by the use of these forms—whether or not they were cheaper could not be determined.

J. V. DAVIES,* M. AM. SOC. C. E.—The only thing the speaker has against this paper is its great brevity. The author has described a piece of tunnel work which has two peculiar and important features: first, the rapidity of the driving; and, second, the use of a "pioneer" heading. Mr. Davies.

To have done the amount of driving in the headings which was accomplished on this work for one month, is one thing, but to continue that work at the rates actually obtained, an average speed of 24 ft. a day for 7 days a week in one heading, and for 20 ft. a day for 7 days a week in the other heading, is really a wonderfully fine piece of work.

It indicates very clearly an extremely perfect organization in every department, and the speaker presumes that it is to be understood, from Mr. Lauchli's discussion, that that progress was in part due to the fact that the conditions, as they developed in the driving, and the conduct of the work, were almost perfect. There were no high temperatures; there was no entrance of hot water, as is so common in mountain ranges, and, in fact, very little water at all.

The comparison of that work with the best that has been obtained in the United States and elsewhere is interesting. The only tunnel in America (for which the speaker has figures) which exceeds the Rogers Pass monthly record (and that probably was only for an exceptional month), was the Red Rock Tunnel, built in 1901, in which a speed of 1 061 ft. for the month was attained; but that was in soft rock, where the boring was done with hand-augers.

The other tunnel to which the speaker refers is the Elizabeth Tunnel, on the Los Angeles Aqueduct, where Leyner drills were used in gneiss rock, and there the maximum progress was 641 ft. a month.

In the Roosevelt Tunnel, in Colorado, in granite, the speed was only 435 ft. a month. There, also, Leyner drills were used.

In an extensive undertaking of tunnel construction which the speaker's firm carried out in Mexico, a few years ago, heading progress was obtained, in hard limestone rock, as high as 536 ft. a month, using Leyner drills. The use of these drills has made a very marked increase in the rapidity of tunnel work.

Now, take the foreign tunnels: in the Simplon, in rock of a character probably very similar to this—hard, gneiss rock—a speed of 685 ft. was attained; in the Loetschberg Tunnel a rate was attained, in the north heading, in a hard limestone, of 1 013 ft., whereas in the south tunnel the rate was only 545 ft.; so that this Rogers Pass Tunnel work stands out pre-eminently as the most rapid that has been accom-

* New York City.

Mr. Davies.

plished in America up to the present day, and is almost equal to anything that has been done elsewhere.

There are various questions which arise from reading this paper, regarding which it would be of considerable value to the membership to have further information, and the speaker hopes that the author may feel willing to go outside of the scope of the paper as presented and give some further information which would add materially to its value.

The particular point of great interest is the value of the "pioneer" tunnel. The author refers to it briefly in the paper as an economical question, and it would be of much value if he could add something in the nature of a balance sheet, having on one side the advantages obtained from the construction of the additional heading, and on the other side the increased cost of driving two heading excavations, as was actually done.

The excuse and reason for a "pioneer" tunnel are unquestionably to increase the speed of construction of the main tunnel, in which there is a large bench to take out, as is involved in the enlargement of such a structure as this double-track railroad tunnel, where the value of the time element, in removing the bench and enlarging to full size, is the main factor involved on the one side of the balance sheet.

There is no doubt that speed can be attained by the driving of a "pioneer" tunnel, and undoubtedly in this case, as the author states, there was warrant for its construction.

Several of those discussing the paper have made remarks as to how the "pioneer" tunnel originated, but it seems to the speaker that any one who has studied the construction of the Simplon Tunnel, as described very fully by Sir Francis Fox,* would be satisfied that the use of the gallery in that work gave the idea from which the "pioneer" tunnel was adopted in this work.

It was used in that work unquestionably for the purpose of ventilation, for transportation and drainage, and to expedite the work.

On the other hand, there was another guiding reason in the Simplon for the adoption of the gallery, as the plans for that tunnel contemplated two single-track railroad tunnels, approximately 55 ft. apart, to be built for east- and west-bound traffic, respectively, and the "pioneer" tunnel was located as the side-wall heading for the second tunnel. It is now being enlarged, or has been in the last few years, to make the second tunnel; but it was located in that position unquestionably for the same purposes as the "pioneer" heading in the Rogers Pass Tunnel was driven, having in mind, undoubtedly, later enlargement for the second tunnel.

* "The Simplon Tunnel", *Minutes of Proceedings*, Inst. C. E., Vol. CLXVIII (1906–07), p. 61.

In the Simplon Tunnel the gallery was lined with the permanent side-wall construction at the same time. Mr. Davies.

In the Rogers Pass Tunnel, as described, there were none of the difficulties which were encountered in the Simplon Tunnel and made the use of a "pioneer" tunnel there so vital to the success of the undertaking.

In the Simplon Tunnel, the "pioneer" tunnel (or gallery, as it was called) was carried right through from end to end, and the gallery was enlarged so as to make a passing siding for trains in the center of the tunnel.

The speaker will be quite interested to obtain from the author at a later date some information as to what pressure he used in the ventilating system, with the Connersville blowers, under the conditions developed in driving this long-distance tunnel. The difference between any short tunnel and one of this length, with no intermediate shafts and no intermediate access, is one of the features of this undertaking which is of very great importance. The ventilation question becomes of the utmost importance, and the pressures at which the ventilating apparatus was operated to produce the forced draft for which the Connersville blowers were used, is of considerable interest.

Another matter on which the speaker thinks some further information would be of considerable benefit to the Society is a statement as to the detailed plan of the bonus system which was adopted for the acceleration of labor, as only a vague reference is made to the subject in the paper. The speaker would also be glad to have a schedule of the rates of wages paid to the men on that work.

S. A. KNOWLES,* ESQ.—In reference to the speed at the Rogers Pass Tunnel, Mr. McIlwee, the original contractor, who was responsible for the methods and organization, had had similar contracts at the Roosevelt Drainage Tunnel, in Cripple Creek, the Laramie-Poudre Tunnel, and several others, in which he had been successful in maintaining a high average footage. The organization which was assigned at the Rogers Pass Tunnel had been with him on his previous undertakings, and thus their combined experience enabled him to obtain such desirable results. Mr. Knowles.

An essential factor in obtaining a high and uniform footage was the ventilation. The speaker had an opportunity at one time to test the ventilating system, which comprised 12 000 ft. of practically straight 18-in. steel pipe of No. 16 gauge. A No. 7 Root blower, running at 100 rev. per min., gave a displacement of 6 500 cu. ft., and the indicated horse-power required for either blowing in or exhausting this quantity of air per minute was about 20.

* Sault Ste. Marie, Mich.

Mr. Dougherty.

R. E. DOUGHERTY,* M. AM. SOC. C. E.—The method used in driving this tunnel, which distinguishes it from the methods utilized in similar instances, involves primarily the so-called "pioneer tunnel." The arrangement is one which is somewhat new in tunnel driving, but the fact that the necessary results were secured by the contractors and the railroad company speaks for its success.

In sending out invitations to the contractors, the Chief Engineer of the Canadian Pacific Railway called attention to the fact that time was a very considerable factor, to such an extent as to be worth about $750 per day, and those who have had anything to do with railroad operation can very readily appreciate the significance of the time element. It is altogether possible that the tunnel might have been constructed by the so-called American methods, at a lesser cost, but the fact that all American records were broken, and the maximum results obtained by European methods approximated, would justify the means used.

Furthermore, from the standpoint of economy, reference might be made to an article by Mr. Sullivan, Chief Engineer of the Canadian Pacific, which appeared in one of the engineering periodicals, in which he states that the actual cost of construction was approximately $5.00 per cu. yd. of the main heading, from portal to portal, which included the cost of the pioneer tunnel, 5 miles of railroad to the site of the work, overhead charges, and all other costs involved. Furthermore, other bids secured by the railroad company ranged from $8.00 to $11.25 per cu. yd., although an estimate of $5.50 per cu. yd. was given by one contractor, based on the American method, but calling for a much greater length of time than was actually consumed. As a basis for comparison in the matter of progress, the maximum rate per month per heading attained at the Rogers Pass Tunnel was 946 lin. ft.; this approximates very closely the maximum rate of 1 013 lin. ft. per month attained in the construction of the Loetschberg Tunnel, in Switzerland.

In making a comparison of the methods used in the construction of other long tunnels, the only work which appears to have been on a similar basis is that involving the Simplon Tunnel in the Alps between Italy and France. The Simplon Tunnel was constructed for a single track, with a smaller auxiliary tunnel which was designed to become a part of a future parallel single-track tunnel, the prime purpose of the auxiliary tunnel having been to permit adequate drainage, as well as to facilitate the handling of material, etc. Without this auxiliary tunnel, it would have been almost impossible, in all probability, to construct certain portions of the Simplon Tunnel. In the case of the Rogers Pass Tunnel, however, the pioneer or

* New York City.

auxiliary tunnel had no relation whatever to drainage, inasmuch as apparently ideal conditions were encountered. Furthermore, the position of the pioneer tunnel, with respect to the main heading, was such as to render it of comparatively small value for drainage purposes, had unfavorable conditions of that character been encountered. Mr. Dougherty.

A careful study of the paper and other literature appearing from time to time in engineering periodicals certainly justifies the conclusion that, although the method used was not, in all probability, the cheapest that could have been adopted, nevertheless, the results were unquestionably consistent with the combined elements of economy and time.

One feature to which attention is attracted is the fact that only 1½ miles of the tunnel will be lined. It would seem that this may be a possible source of trouble in later years, especially as experience in the eastern section of the country indicates that, in a number of instances, tunnels unlined at the time of construction have had to be widened and lined over traffic at an abnormal expense; and, even under the most favorable conditions, it would seem that experience justifies the excavation of a tunnel section of sufficient area to permit at least of later lining without the necessity of excavating over traffic.

Congratulations are heartily extended to the author for his contribution to the literature of the Society, and primarily for the part which he has taken in the work under discussion.

C. R. Hulsart,* Assoc. M. Am. Soc. C. E.—Milton H. Freeman, Assoc. M. Am. Soc. C. E., Resident Engineer on the East River Tunnels, joins the speaker in considering the pilot heading somewhat as a horizontal shaft. Of course, its length is greater than the average length of shafts in tunnels, but it is much cheaper per foot. To justify pilot headings on a purely economical basis would be rather difficult. They must be justified by their convenience and the facilities they afford for expediting the work. For instance, the Walkill Pressure Tunnel, one of the Catskill Aqueduct tunnels, more than 23 000 ft. long, had six shafts ranging from 330 to about 500 ft. deep. Of course, such a pilot heading would not be applicable to pressure aqueducts, but, taking that as an example, for those six shafts at a cost of $200 per ft. for the sinking and lining (not a bid price, but cost), such a drift could have been built for one-half the length of the tunnel, or, in other words, shafts about ⅜ or ½ mile apart could have been used, instead of ¾ mile apart. Mr. Hulsart.

Tunnel ventilation is an interesting subject. The wooden stave pipe gives a certain rigidity, which was lacking in the 12-in. galvanized-iron pipe used throughout the Catskill Aqueduct. It permits of the exhaust method, which most tunnel engineers generally favor. With the galvanized-iron pipe, the exhaust method is somewhat disastrous, because in exhausting, while blasting, the pipe frequently col-

* New York City.

Mr. Hulsart.

lapses. The speaker has seen several hundred feet of pipe collapse, and this the wooden stave pipe would not do. In ventilating the Newark Bay Tunnel on the Passaic Valley Sewer, R. H. Keays, Assoc. M. Am. Soc. C. E., used a 6-in. pipe, and blew air into the heading at a pressure of 7 lb. at the compressor, which gave excellent results. The ventilation was effective for more than 1 mile. The length of the tunnel was 11 000 ft., and one heading was considerably longer than 1 mile. The men were never overcome by smoke or fumes.

On the Catskill Aqueduct, when air had to be driven for some distance, with a fan which could create a pressure of perhaps only 7 oz., a relay method was sometimes adopted, with one or two fans in the tunnel for blowing in or exhausting.

The contractors for the Rogers Pass Tunnel made extensive use of compressed air, a plan which not many New York contractors would follow, to the same degree. Compressed air is a very expensive form of power, especially (as in this case) when compressed to 1 000 lb., for use in traction engines, trucks, and blowers. On the Walkill Pressure Tunnel, which was particularly well planned, some tests were made with air compressed to 100 lb. and used for pumping purposes. Considering the whole system, from the power that went into the motors operating the compressors, to the water pumped at the tunnels, the efficiency was found to be about 7½%, and that of electric pumps, in small units, was about 55%; in other words, electricity was from seven to eight times as efficient as air compressed to 100 lb.

To compress air to 1 000 lb. requires two and a half times as much power, and it is used in any ordinary motor pump, hoist, or traction engine at a pressure of about 100 or 150 lb., so that the efficiency of such air-driven machinery would be about one-twentieth of that of electrically-driven machinery.

The Rogers Pass high-pressure plant required 1 500 cu. ft. at each end of the tunnel, or 3 000 cu. ft. of free air raised to a pressure of 1 000 lb. This involved the consumption of about 3 tons of coal per hour, during the time the two compressors were running (and it is assumed that they ran most of the time). Only one-twentieth of this fuel would have been required if electric power had been used for traction, power pumps, and blowers.

The shovel plates mentioned reminded one of the tendency, on a great many jobs, where everything is being sacrificed for speed, to forget to put them down, or perhaps eliminate them altogether. On one of the aqueduct jobs, where shovel plates were tried, the same gang mucked up the same quantity of rock in 30% less time with these plates than without them.

The cost of making records in driving in relatively small tunnels is worth studying. In the Catskill Aqueduct tunnel—equiva-

lent to a single-track railway tunnel—records were sometimes rather expensive, as the progress in such a tunnel is limited to a great extent by the speed of mucking. If the speed is increased the muck is increased, more muckers are required in a smaller space, and the men are in one another's way. As an example of this, in one of the headings of the Walkill Pressure Tunnel, where the progress had been about 80 ft. per week, each man was handling about 2 cu. yd. of solid rock in 8 hours. The progress was increased to about 90 ft., but in order to do that, the number of muckers was increased, and each laborer handled about 1½ cu. yd. of solid rock in 8 hours. The progress was then increased to somewhat more than 100 ft., and each laborer handled a little more than 1 cu. yd. of solid rock in 8 hours. In view of these facts, another firm of contractors, carrying relatively small overhead cost, separated, as far as possible, the drilling and mucking operations. The firm lost sight of records to a large extent, and went in for economical tunnel driving. Three gangs of drillers and three gangs of muckers were used. While the muckers were at one heading, the drillers were at the other, and when they finished drilling and shooting one heading, they exchanged headings with the muckers. The mucking was very efficient. The speaker does not know how much rock each man handled, but, it was generally considered as a very economical job. Mr. Hulsart.

J. G. SULLIVAN,* M. AM. SOC. C. E. (by letter).—The object of this discussion is to correct some erroneous accounts and misstatements which have developed in previous discussions. The most flagrant of the latter was the statement, by Mr. S. A. Knowles, that the credit for the quick work done at Rogers Pass Tunnel was due to Mr. McIlwee, who was the original contractor and was responsible for the methods and organization. This is very far from the truth. The facts of the case are as follows: Mr. Sullivan.

During January, February, and March, 1913, while the engineers were working on plans for the building of this tunnel, the writer had two or three conferences with Mr. Dennis, whose office at that time was in Winnipeg, and, on March 13th, 1913, he reported his ideas on the subject to the management of the Company in the following terms:

"Referring to the progress that we hope to make in driving of Rogers Pass Tunnel. I advised you in my report of October 22d regarding the relative speeds of driving tunnels on the American continent compared with those that have been driven through the Alps. I have given the matter considerable study since, and have come to the conclusion that the European method of driving a small lower heading and stoping out the remainder of the tunnel would be too expensive on this side, on account of the difference in the cost of labor.

* Winnipeg, Man., Canada.

Mr. Sullivan.

"I have been thinking out and studying methods that would tend to expedite this work. I first thought of driving a heading in the center of the tunnel, about 9 ft. by 12 ft., and keeping this heading close to the bench, carrying the air pipes over the muck in front of the steam shovel and into the heading. I still believe that this method in rock that will stand, is better than an upper heading. Mr. A. C. Dennis, however, suggested driving a pioneer tunnel and taking out an upper heading through shafts into this tunnel, taking out the rest of the bench with steam shovels. I pointed out to him that this was impracticable for the reason that from an upper heading you cannot drill to the bottom of the tunnel, and therefore would have to clean up all the muck in the bench before you could put in a round of breast holes to break more rock. I have now made plans showing a combination of my ideas and Mr. Dennis', which I think is well worth studying. The plan is to drive a small working pioneer tunnel, 8 ft. by 8 ft. underneath the main tunnel. I am sending you this for your information and, further, if this method should be adopted, that Mr. A. C. Dennis may have the proper credit for first suggesting a pioneer tunnel."

This was about a year before the writer ever saw or ever heard of Mr. McIlwee. So much for the methods adopted in the construction of this tunnel.

As to the statement that Mr. McIlwee was the original contractor: Mr. McIlwee never had any contract with the Canadian Pacific Railway Company in connection with this work. In the fall of 1913, the general contractors sub-let a portion of the work of driving the pioneer headings and the center heading to Mr. McIlwee. There immediately appeared, in some Denver papers, a notice to the effect that Mr. McIlwee had a contract for a 5-mile tunnel in Canada. The following is a quotation from the writer's report to the Management as to what was meant by these notices:

"The understanding was that he would bring men from Colorado and drive the outside pioneer tunnel at so much per foot at a certain rate of speed. The contractors were to pay him a bonus on any excess over this specified rate of speed. Contractors to furnish the cars, air, steel, and all other plant, as I wired you before, the result being that these men were working at piece work. If they do not make the speed guaranteed, they can be put off the work and nobody will suffer, as the entire plant is owned and controlled by the contractor. A man without one cent but brains, can enter into an agreement of this kind, while it takes capital to enter into a contract to build a five-mile tunnel."

In other words, Mr. McIlwee, on this particular work, might be ranked with the grade of contractors known as stationmen on railway construction work.

In reference to the discussion by Mr. E. Lauchli: Mr. Lauchli, in attacking this method of doing work, quotes the writer as authority for prices bid, without giving the full quotation, and leaving an incorrect

impression. In the article, from which the writer thinks the quotation was taken,* the full paragraph reads as follows: Mr. Sullivan.

"I may add further that, in reply to my invitation of April 8, 1913, the contractors who are doing the work, having in mind the method which was later adopted and which was suggested by myself and one of their Engineers, bid $6.10 per cu. yd., with a time limit of 42 months from date of signing contract. Other responsible and supposedly expert tunnel contractors bid from $8 to $11.25 per cu. yd., with time limits varying from 42 to 48 months. I do not know what method these latter contractors proposed to employ, but I always presumed it would be some modification of the European method."

All contractors had the same information, and the majority of those who bid sent men on the ground where they could see the character of the rock, from unbroken rock exposure, for practically the entire distance of the tunnel, from inspection along the railway, and also over the bare rock cliffs. These cliffs extended for a height of practically 6 000 ft. above the tunnel, which explains how absurd it would be to attempt to make borings in order to get any further information than was apparent from the surface; therefore, the meaning of the phrase previously quoted is entirely different from that placed on it by Mr. Lauchli. It simply indicates that the parties having in mind this method of boring the tunnel had confidence enough in it to know that they could build the tunnel 30 or 40% cheaper than by methods previously used.

Mr. Lauchli further states that his figures of "the cost of driving this bore, with a bottom heading, would be $5 per cu. yd., exclusive of contractor's profit." If this was a fact, all the writer can say is, that Mr. Lauchli's clients must do very well if they can make the proverbial German 1% profit, that is, of course, providing they get any work.

Mr. Keays is under a misapprehension when he states that "no heading was driven in the main tunnel, using the pioneer heading to work from." All the heading in the main tunnel was driven from drifts cut into that tunnel from the pioneer, and all the material from this main heading was carried through the pioneer tunnel, either directly to the outside, or around the shovels to standard-gauge cars back of where the shovels were working in the main tunnel.

Regarding Mr. Thomson's discussion: This is very interesting, and the writer is heartily in accord with his idea of paying homage and doing honor to the remarkable engineers of the past age, and especially to Major Rogers, whom the writer had the pleasure of seeing at a meeting of the Society, in Milwaukee, Wis., some 29 years ago. In this particular detail of the location of the Canadian Pacific Railway, however, Mr. Thomson has a wrong idea. The distance around by the Columbia River, from Beavermouth to Revelstoke, is 163 miles,

* *Engineering News*, February 24th, 1916.

Mr. Sullivan.

96 miles longer than the line located by Major Rogers, and for the traffic carried in 1912 and 1913, when the question of double-tracking and revising the line was being studied, it was seriously proposed to abandon the Rogers Pass route and build by way of the Columbia River, as almost enough could be saved in the cost of operation on this longer line to pay the interest on the construction of the new line, and a great deal more than the difference in the cost of the two lines, had the Company been fortunate enough to build around there in the first place. Nevertheless, the Company is now thankful to Major Rogers, for, had it originally built the line around by way of the Columbia River, the writer is sure that it would never have been abandoned for the present line, which, with the tunnel and heavy business, is more economical, especially in time, than operating the longer distance by way of the Columbia River. The Company should be especially thankful to Mr. Sammy Sykes, the Locating Engineer, who was responsible for the "Loops" on the west slope of the Selkirk Mountains, inasmuch as the original location ran straight down the north bank of the Illicillewaet, where, to this day, signs of some abandoned construction work can be seen, but, in order to save money at the expense of distance, Mr. Sykes put in the "Loops." The result of introducing these "Loops" brought the constructed line into the valley of the Illicillewaet, very close to the West Portal of the Tunnel.

These, the writer thinks, are two instances which illustrate the fact that it is never very safe to be too sure in a criticism. Here are two cases which could be looked on as blunders, as the increased cost of operation, in the one case on account of the heavy grades and the large rise to be overcome and in the other case operating over the longer distance of line without improvement in grades, with a reasonable volume of traffic, would be greater than the interest on the money that was saved in construction, but which really turned out to be a benefit rather than otherwise.

Mr. Davies asks for information regarding the economics of using the pioneer tunnel. To quote further from the writer's report of March 13th, 1913, to the Management:

"This method, of course, is only applicable where the rock will stand without artificial support, at least during the time of construction. Where the material must be artificially supported, then the top heading is the surest, and I think, the best way. The progress of the work by this method, as I said before, depends only on the speed that the pioneer tunnel can be driven. If rock is self-supporting, I see no reason why from 20 to 25 ft. per day could not be made. Placing the cost of driving the small tunnel at $30 per ft., that is the only part of the work that would be rushed under high pressure, and the heading proper can be taken out at least $5 per ft. cheaper than if the work

must be done under pressure, then the bench containing 18 cu. yd. per ft. (neat section) can, on account of there being no interruptions to wait for drilling or cleaning up to put in breast holes or knocking down material in order to get pipes into the heading, at a low estimate, be taken out 75 cents per cu. yd. cheaper, or $13.50 per ft., which would make a saving in excavation of tunnel proper of $18.50 per ft., leaving $11.50 to be taken care of in interest saved account making greater speed. In my report to you of October 22d, 1912, I estimated an annual saving of about $226 000, but all my figures were very conservative, and I took into account only one or two of the larger factors of the extra expense. Mr. Bogue's more accurate figures show a saving of over $370 000. However, his estimate for fuel per h.p. hour was 40% higher than the figure I used, and the price of coal was 17% higher than the price I assumed. His price is more accurate than the one I used, but assuming, for the sake of being conservative, that the average between the two estimates would be approximately correct, that would mean, say $300 000 per year saving, to say nothing of the interest on the $3 000 000 or $4 000 0000 that will be invested in construction, from which we will not be receiving any benefit until the work is completed. Therefore, if this tunnel can be completed one year sooner by using this method, the saving thus made will a great deal more than save the $11.50 additional cost of the pioneer tunnel." Mr. Sullivan.

That these estimates were conservative has been proved by the results, which were better than the estimates. The pioneer tunnel, from the most careful studies of the information at hand, cost about $28 per ft. instead of $30, as estimated. There was a great deal larger difference than 75 cents per cu. yd. between the actual cost of enlarging the tunnel by this method and the estimated cost of enlarging without the use of the pioneer tunnel; and another item, not taken into account in this estimate, was the fact that the pioneer tunnel only had to be driven less than four-fifths of the total distance. This was an indeterminate factor at the time these estimates were made, and the writer purposely omitted referring to it, as it was desired to have the estimates of this untried method conservative in any reports made to the Management.

It has been stated by some that this method is not applicable where there are soft spots in the rock. If the soft rock encountered does not exceed 50% of the total, the writer is confident that this method would still prove more economical than any other which has yet been tried, for the reason that when the soft places are encountered, there is plenty of time to stope out the upper part of the arch and timber it, so that when the steam shovel arrives at those places, there will be no delay whatever, and, instead of having to stope out the entire section by hand, as is necessary in the under-heading method, only about half, or less, of the material in the section requires to be removed in this manner.

Mr. Sullivan.

One word more as to actual costs: To quote further from the report of March 13th, 1913:

"I figure that by this method the pioneer tunnel can be driven for about $30, the main heading for about $40, and that the bench can be taken out for about $54, making a total of $124. There will be incidentals; contractors' profit should not amount to over $20 per ft. Of course, this method of driving the tunnel, working so many drills at one time, will require a larger plant than if only one heading was driven, and that at a slower speed than we contemplate."

The expectations of the Railway Company have been more than realized, as is proved by the speed and the cost of the work. The cost of driving this tunnel through rock, including in this price the cost of driving 19 610 lin. ft. of pioneer tunnel, twelve cross-cuts, each about 40 ft. long, erecting the plant (including freight), the proportionate cost of building about 5 miles of temporary railway tracks, and other overhead charges, plus 10% on all expenditures, will amount to a little less than $5 per cu. yd. for excavation in the tunnel proper.

In conclusion, the writer wishes to say that, in Europe, where it is understood that drill runners get from 90 cents to $1.25 and laborers about 75 cents, the method followed in driving the Loetschberg Tunnel may be both economical and rapid, but all the evidence at hand goes to show that where one pays from $5 to $6 per day for drill runners and from $2.50 to $3.50 per day for laborers, the method adopted is by far the most economical.

Mr. Dennis.

A. C. Dennis,* M. Am. Soc. C. E. (by letter).—The writer is very grateful to those who have been interested enough to discuss his paper, and wishes to thank them.

In reply to Mr. Lauchli, in his criticism of the Railway Company for its lack of geological data for use of bidders, it would appear that, except for the vicinity of the portals, the Railway Company could not, by boring, or other methods, supply information beyond what was available to the contractors for their inspection of the almost unbroken rock exposure from Rogers Pass to Bear Creek. The kind of rock and its pitch are obvious from inspection along the railway, and from the bare rock cliffs above.

The writer is unable to agree that the bottom heading method of tunneling is "the only method known to-day, which insures absolute success, both under favorable and unfavorable conditions." In good ground, it is obviously an economic question, depending to a large extent on the cost of labor. For heavy ground, such as that near the portals of this tunnel, it is believed that the bottom heading system is unsuitable.

* Vancouver, B. C., Canada.

Mr. Dennis.

There was heavy ground near the center of the mountain, in this tunnel, which required timbering. The main heading, from wall-plate level up, was excavated to full section by hand, and timbered by segments from the wall-plate set on rock. When the enlargement and shovel operations reached this point, no delay or damage to the timbering or bench on which the wall-plate was set was caused by blasting or mucking the bench. The work on this section was similar to that of timbering a heading and taking out a bench afterward, except that the muck going out and the timber, pipe lines, etc., in this case, did not interfere with other operations, as would have been the case without a "pioneer" heading.

Mr. Lauchli's figures for bids on this work, and his costs for other tunnels, do not appear to support the bottom heading system as being the cheaper method, even where cheap labor is available.

Mr. Shailer is quite right that 750 boiler h.p. would appear to be inadequate. These boilers, of 750 nominal h.p., however, readily produced 1 000 h.p., by reason of the induced draft. The fuel used was slightly less than the quantity estimated. The fuel estimate in figuring the bid was based on 22 lb. of coal per 1 000 cu. ft. of air compressed to 100 lb. by the gauge.

The compression of air beyond the pressure at which it is to be used, in order to provide for pipe-line losses, is an economic question which was given due consideration. It was calculated that the 8-in. main used was the economic size, and that a larger pipe would not save by reducing frictional losses to compensate for additional first cost, less salvage value, plus labor of putting down and removing. The higher air-pressure requirements noted are the maximum, and only apply for a short period. For a permanent plant, larger pipe would have been justified.

It is doubtful whether modern drills will result in much increase in tunneling speed by the "top heading and bench" system, as suggested by Mr. Keays. The heading drilling may be faster, but the bench drilling and mucking is usually the limiting feature in progress, and hammer drills are inefficient in long down-hole drilling. The writer must disagree with Mr. Keays' statement that the "ventilation between the working face and portal is unimportant", and also that the pressure system is preferable to the exhaust. The exhaust method only requires the mechanical removal of the air from 100 ft. or so of the heading, but the pressure system requires such removal for the entire tunnel length, in order to obtain a clear tunnel. The pressure system tends to mix the fresh air with the smoke and gas, rather than to drive the smoke out bodily. Wooden pipe, in the Northwest at least, solves the ventilating pipe problem, both from an economic and mechanical standpoint.

Mr. Dennis.

Mr. Lavis' words of appreciation are very welcome. The writer regrets that detailed cost figures, which are the real test of any work, have to be withheld to conform with the contractors' policy in this respect, but will go so far as to say that, under like conditions, even if time carried no bonus, he would adopt the pioneer method, unless there was sufficient time to drive the heading, centrally located, entirely through first, and muck the enlargement from one end only, and that never again would he use a top heading in hard rock.

The writer regrets that the report referred to by Mr. Thomson, by the late Virgil G. Bogue, M. Am. Soc. C. E., is not his property, and he is unable to give the Society the pleasure and instruction which was his privilege in studying this masterpiece by his old friend and Chief. Mr. Thomson, as well as many others of the construction days of the Canadian Pacific Railway, will regret that Major Rogers' name, like others who helped in the great work, will soon be forgotten on that railroad. The Rogers Pass Station has been abandoned, and the name of the Rogers Pass Tunnel has been officially changed to Connaught Tunnel.

To Mr. Davis, the writer would say that the idea of a pioneer heading originated in the desire to get away from the congestion, smoke, general confusion, and interference of one operation with another, observed in tunnel driving, and to provide muck in large quantities for handling by shovel. His work in coal mines, with the air course run with the main entry, suggested the pioneer as a means to this desired end. The Connersville blowers were used exclusively for exhausting from the working faces, and would produce 7 lb. below free air pressure. This provided satisfactory ventilation through 12-in. pipe for 1½ miles, at which point a second blower was put in, working as a booster on the same pipe line.

The general wages paid were 40 cents per hour to drill runners, and 35 cents per hour to others. The bonus probably averaged 25% in addition to these rates.

To Mr. Knowles, the writer has to say that the contractor he mentions is the one referred to in the paper as having a sub-contract for labor and explosives in certain headings for a short time, but whose sub-contract was cancelled on account of unsatisfactory work. Mr. White also seems to have been misinformed in crediting this former sub-contractor with the speed made. He and all his organization left the work a year before Mr. White's visit, at which time only a short length of heading had been driven in the rock.

In regard to Mr. Dougherty's point, as to whether this tunnel could not have been built for less cost by other methods, it is difficult to say. The writer does not think so, but would be much interested in a com-

parison of costs of other tunnels with those quoted from Mr. Sullivan's article, due allowance being made for extra cost for long tunnels, and bearing in mind that this tunnel was not in "ideal" or "made-to-order" ground. The West Portal earth section was very difficult, and the rock section was hard to break, as illustrated by the average explosives used in the pioneer heading, that is, 15 lb. of 60% gelatine per cu. yd. Mr. Dennis.

Mr. Dougherty's point, that all excavation should be taken out during construction to allow for lining, is well taken. The extra excavation can be done during construction for probably 10% of the cost of enlarging under traffic. No tunnel is entirely safe until it is lined.

Paper No. 1391

UNUSUAL COFFER-DAM FOR 1 000-FOOT PIER, NEW YORK CITY*

By Charles W. Staniford, M. Am. Soc. C. E.

With Discussion by Messrs. Frederic R. Harris, D. A. Watt, C. A. Wentworth, Thomas H. Wiggin, T. Kennard Thomson, Charles S. Boardman, William M. Black, and F. E. Cudworth.

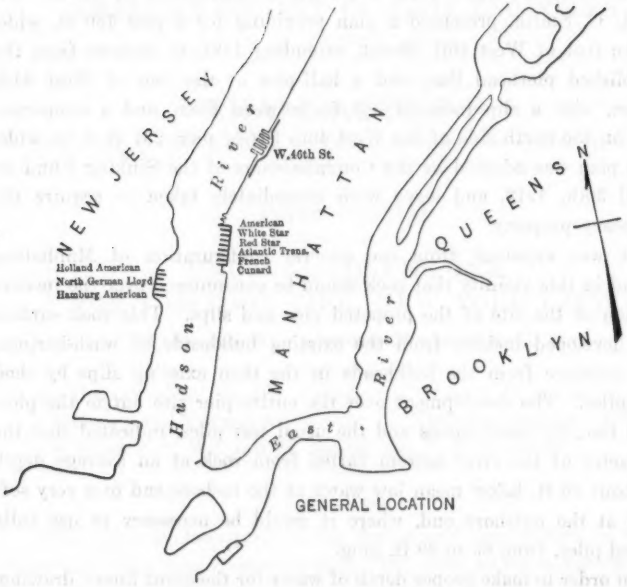
Synopsis.

This paper is descriptive of the design and construction of a steel sheet-pile coffer-dam of unusual type. This dam, so far as known, is the highest on record.

In outline the coffer-dam is a cellular steel sheet-pile structure, designed for a pressure head, of soft mud and water, of about 65 ft., having the cellular spaces filled with earth and clay to form the water seal, and held against the external pressure by an embankment of rip-rap or broken rock. All the steel sheet-piling forming the cellular spaces or "pockets" is in single pieces, many of which are more than 70 ft. long.

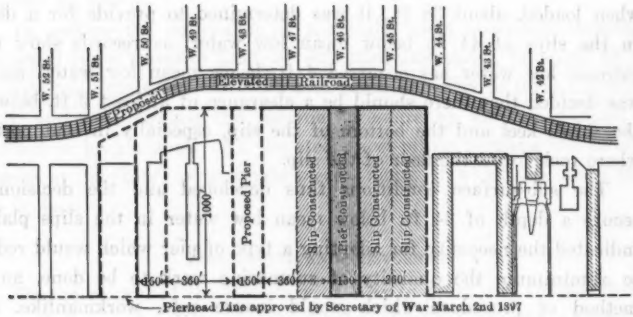
Descriptive and Historical.

On the refusal of the Secretary of War to grant any further extension of the pierhead line in the Chelsea District, thereby preventing permanent additions to the present piers and thus making it impossible to dock the new large transatlantic liners—more than 900 ft. long—at that locality, the City of New York was obliged to secure another site



* Presented at the meeting of March 7th, 1917.

which would permit the construction of piers long enough for such vessels; and on April 10th, 1913, the Commissioner of Docks, Mr. R. A. C. Smith, presented a plan providing for a pier 150 ft. wide, at the foot of West 46th Street, extending 1 000 ft. inshore from the established pierhead line, and a half-pier at the foot of West 44th Street, with a slip room of 360 ft. between them, and a temporary slip, on the north side of the West 46th Street pier, 237 ft. 6 in. wide. This plan was adopted by the Commissioners of the Sinking Fund on April 30th, 1913, and steps were immediately taken to acquire the necessary property.



It was apparent from the general configuration of Manhattan Island in this vicinity that rock would be encountered over the inshore portion of the site of the proposed pier and slips. This rock surface was developed inshore from the existing bulkheads by wash-borings, and outshore from the bulkheads in the then existing slips by shod test piles. The development over the entire pier site out to the pierhead line, by these means and the usual test piles, indicated that the character of the river bottom varied from rock at an average depth of about 20 ft. below mean low water at the inshore end to a very soft mud at the outshore end, where it would be necessary to use fully lagged piles, from 85 to 89 ft. long.

In order to make proper depth of water for the giant liners, drawing, when loaded, about 38 ft., it was determined to provide for a depth in the slips of 44 ft. below mean low water, as records show that extreme low water has occurred 4 ft. below mean low water, and it was decided that there should be a clearance of at least 2 ft. between the ship's keel and the bottom of the slip, especially in that portion where rock forms the floor of the slip.

The sub-surface conditions thus developed and the decision to secure a depth of 44 ft. below mean low water in the slips plainly indicated the necessity for adopting a type of pier which would reduce to a minimum the quantity of submarine work to be done, and a method of procedure which would insure safe, workmanlike, and economical construction. Accordingly, a solid filled type was adopted for the inshore portion, about 220 ft. long, consisting of concrete retaining walls, to retain the filling and provide wharfage face, founded on bed-rock, thus utilizing the rock bottom over this portion of the pier area.

GENERAL LOCATION

DETAILED LAYOUT

WEST 46th STREET IMPROVEMENT

FOR LONG STEAMSHIP PIERS

FIG. 1.

The larger quantity of rock excavation necessary with submarine blasting over that within the coffer-dam, in order to make certain that the excavation would be carried to the lines and grades required; the advantage of being able to control the surfacing of the rock for the pier and slip walls, and to prepare the rock surface for the foundation of these walls; and the desirability of building these walls "in air"; all indicated the wisdom of prosecuting the work within a coffer-dam to be built so as to enclose the entire site of the work, extending from the center line of West 44th Street northward to the center line of West 47th Street, a distance of 780 ft.

Design.

Having decided on the coffer-dam method of construction, the type to be used was made the subject of careful consideration. The area to be enclosed prohibited the use of bracing, and the unbraced steel sheet-pile type of coffer-dam was naturally suggested. Coffer-dams of this type had been used previously by the United States Government, at Black Rock and at Havana. There it was expected that the filling within the pockets would make them stable against the external pressure, unaided, but in both cases it was found necessary to place an embankment of stone against the pockets, and in the case at Havana, extensive bracing to the *Maine* was also placed, in order to stop the continuous inward movement of the coffer-dam.

In a coffer-dam of this type the internal frictional resistance of the filling takes the place of the cohesion in a solid, and analysis would show that, with material having a natural slope of not more than 3 to 1, failure would occur in vertical as well as horizontal shear, though the resultant passes through the middle third of the base.

The material overlying the rock at West 46th Street is a clayey mud, the natural slope of which is probably not as good as 3 to 1, thus prohibiting its use to obtain stability.

It had been decided to dredge over the site of the coffer-dam to 30 ft. below mean low water, leaving the remaining material to furnish support for the sheet-piles. The difficulty of removing the material from within the pockets and substituting better, as well as the greater cost of a coffer-dam of this type, due to the larger quantity of steel sheet-piling required, led to the adoption of the type shown by Fig. 2.

It should be noted that, where no embankment is placed against the pockets, the sheet-piles will be subjected to the pressure of the entire depth of filling at all times, and as the water after pumping may be expected to remain in these pockets for at least one-half their depth, if not more, as was the case at Havana, these sheet-piles will also be subjected to this hydrostatic pressure, necessitating a closer spacing of the diaphragms than where embankments are used.

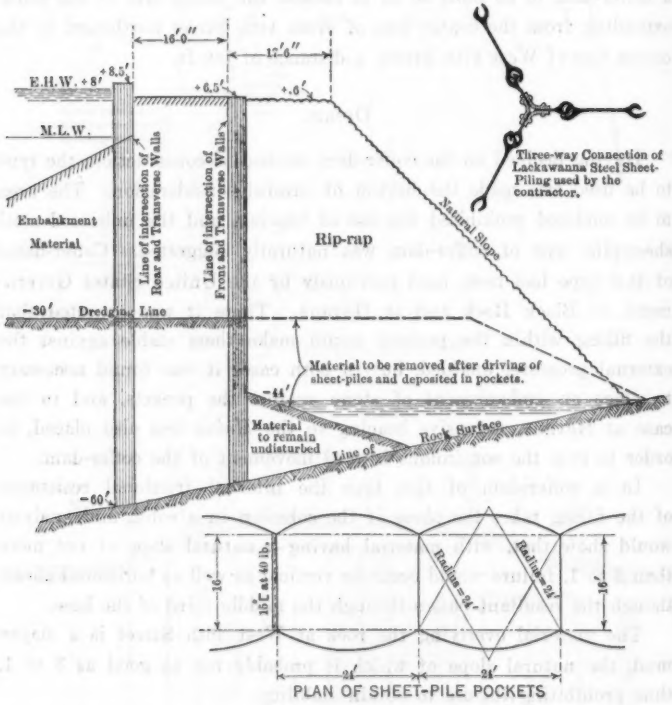


FIG. 2.

In the type of coffer-dam adopted, the sheet-pile pockets are used merely as a water seal, being supported against the external hydrostatic pressure by an embankment of rip-rap inside, and against the pressure of the rip-rap, during construction and before pumping, by a smaller embankment of earth outside.

This type of coffer-dam was adhered to, except along the crib bulkhead at West 47th Street, where, in place of the sheet-pile pockets, a single line of steel sheet-piling was driven, with an embankment of rip-rap in front, the space between the sheet-piles and the crib being filled with earth. Also, because of the limited space between the inner end of the West 44th Street Pier and the — 44-ft. rock contour line, two large cylinders filled with rip-rap were substituted for the pockets and embankment at this point. The only leaks, as described later, were encountered at these two places.

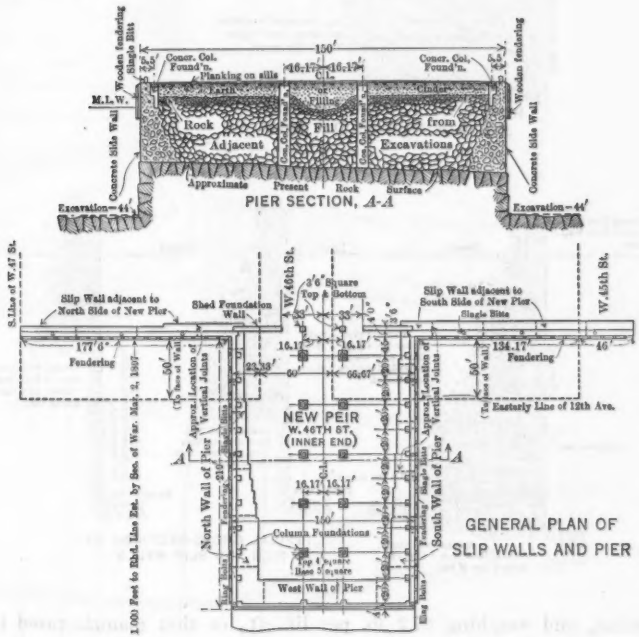

FIG. 3.

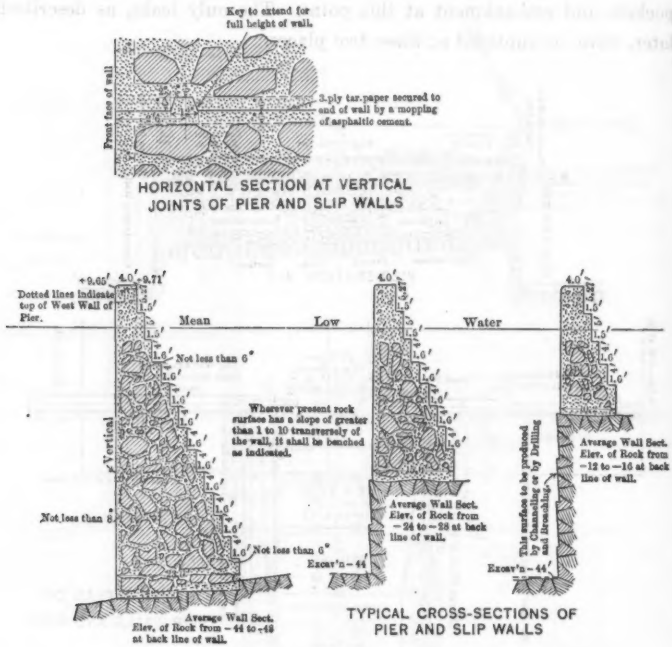
Pockets 6 and 22 were made 12 ft. wide and provided with sluiceways at a grade of 1 ft. below mean low water. These were put in chiefly to maintain the water at the same level on both sides of the coffer-dam during the construction of the closing pockets, thus avoiding any unbalanced pressure due to changes of tide before the placing

of the rip-rap embankment, and also to let the water into the coffer after the completion of the excavation and construction.

The specifications called for the following:

"The steel sheet-piling shall be rolled, interlocking sheet-piling similar and equal to that manufactured by the Carnegie Steel Company, type M-104, $\frac{3}{8}$-in. web, and weighing 38 lb. per lin. ft., or that manufactured by the Lackawanna Steel Company, $\frac{3}{8}$-in., straight web



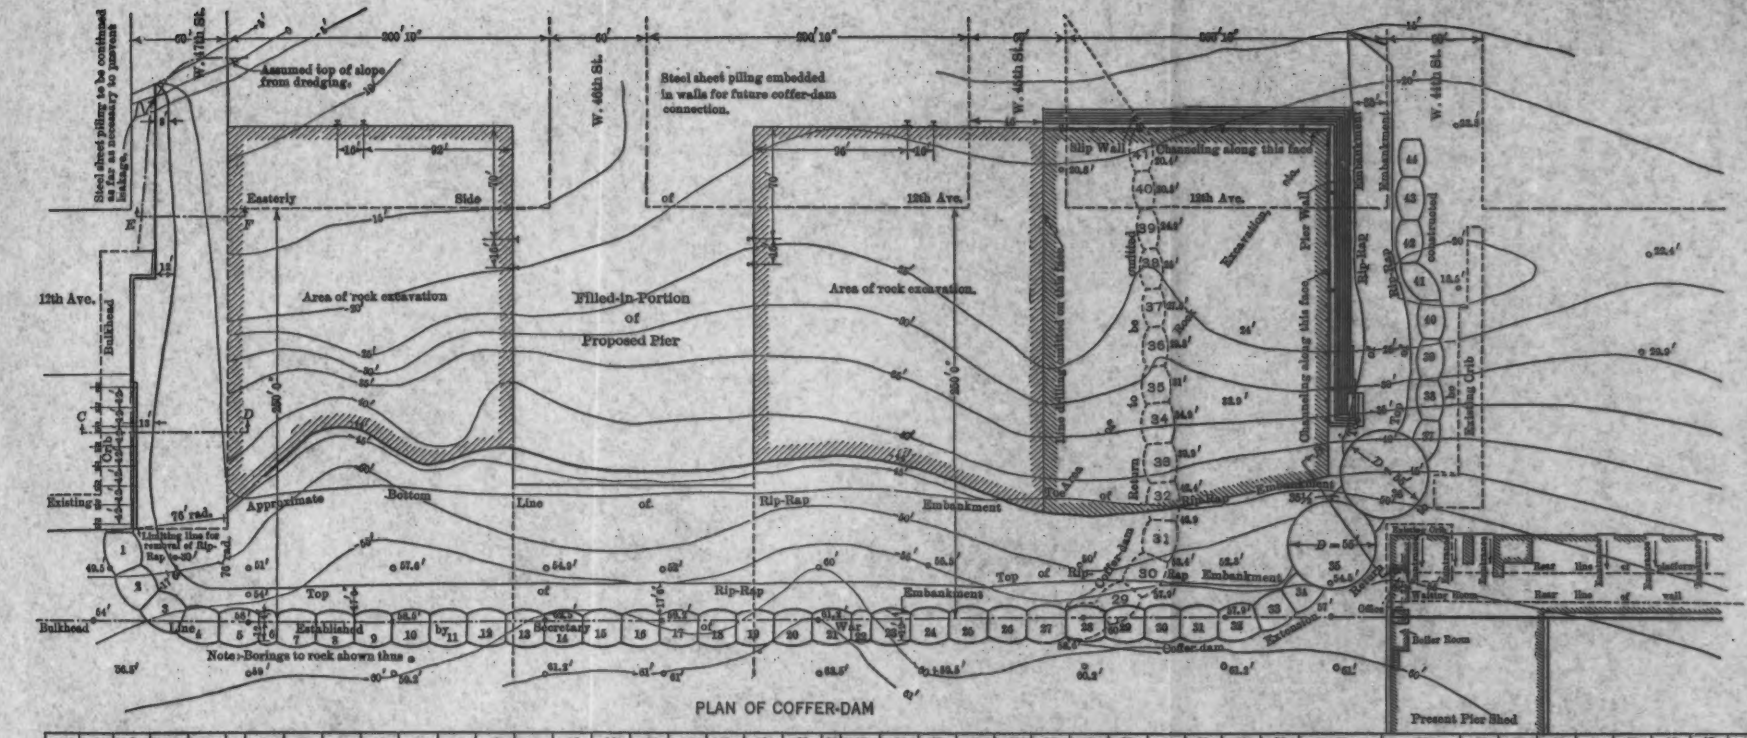


FIG. 4.

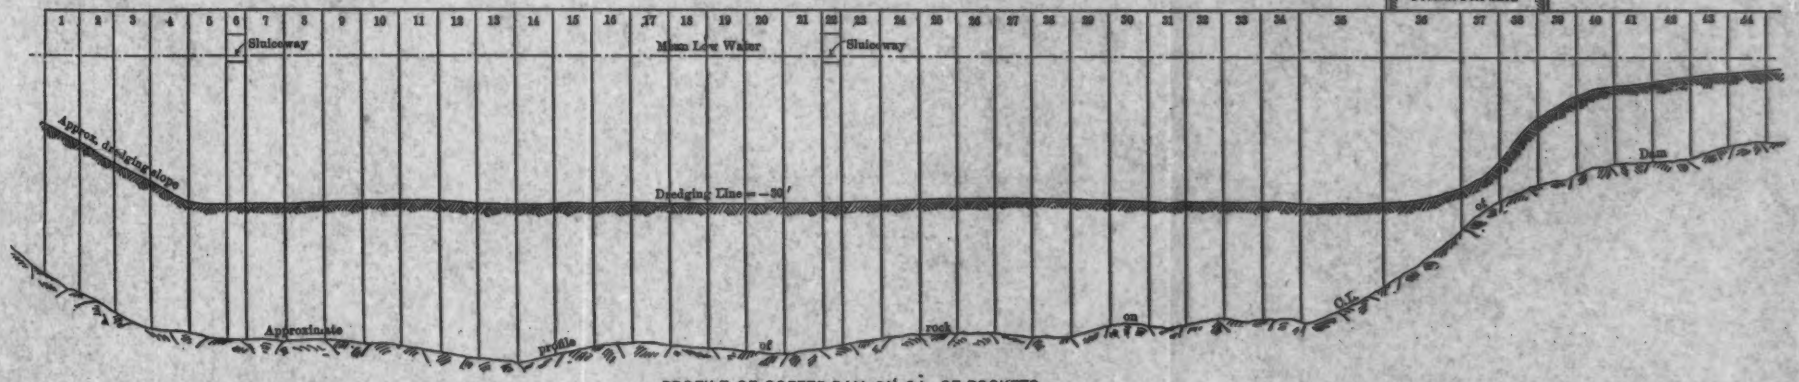

section, and weighing 37.2 lb. per lin. ft., or that manufactured by the Jones and Laughlin Steel Company, 12-in., special I-beam section, and 5-in. locking bar, weighing, together, 36.1 lb. per lin. ft., and shall develop a tensional strength in the interlock between two adjacent piles, when tested on pieces about 3 in. long, of not less than 9 500 lb. per lin. in."

The contractor selected the type made by the Lackawanna Steel Company, shown on Fig. 2, which proved very satisfactory. The

PLAN OF COFFER-DAM

PROFILE OF COFFER-DAM ON C.L. OF POCKETS

three-way connection pile used at the intersection of the transverse and outer walls of sheet-piling weighed about 85 lb. per ft.

Stresses in Sheet-Pile Walls of Pockets.

Due to the pressure of the retained filling, the sheet-piles are all in tension transversely. Their resistance to this tension is limited by the strength of the interlock, which tests show will exceed 9 000 lb. per lin. in. When the filling is done in a proper manner, the pressures from each side of the transverse walls will balance each other, and the tension will be entirely due to the pressure against the longitudinal sheet-pile walls.

$$t = \frac{p\,d}{12};$$

where t = the tension, in pounds per linear inch, in the transverse walls;
p = the pressure, in pounds per square foot, against the longitudinal walls at the level considered; and
d = the distance between the transverse walls, in feet.

The longitudinal sheet-pile walls are arcs of a circle, and, assuming them to be subjected to a radial pressure from the filling, the tension per linear inch is:

$$t_1 = \frac{p\,R}{12},$$

where R is the radius, and $t_1 = t$ where $R = d$.

The original plan required the pockets to be filled with the material remaining on their inshore sides after dredging. It was considered possible, therefore, that they might be entirely filled before depositing the rip-rap embankment. In this case the sheet-piles would be subjected to the pressure of about 58 ft. of filling. Assuming the weight of the submerged river mud at 80 lb. per cu. ft. and its natural slope at 3½ to 1,

$$p = 0.57 \times 80 \times 58 = 2\,600 \text{ lb. per sq. ft.},$$

and as $r = d$, the maximum stresses in the longitudinal and transverse walls are equal and given by

$$t = \frac{2\,600 \times 24}{12} = 5\,200 \text{ lb. per lin. in.}$$

The possibility of avoiding unduly straining the sheet-piles by depositing some of the embankment before completely filling the

pockets was considered, and was actually found advisable, as explained later.

Tests on Model Embankment.

To obtain information regarding the probable behavior of a rip-rap embankment under various conditions of pressure, some tests were made with a model, one-twentieth the size of the embankment, placed against the inshore side of the sheet-pile pockets, or 42 in. in height

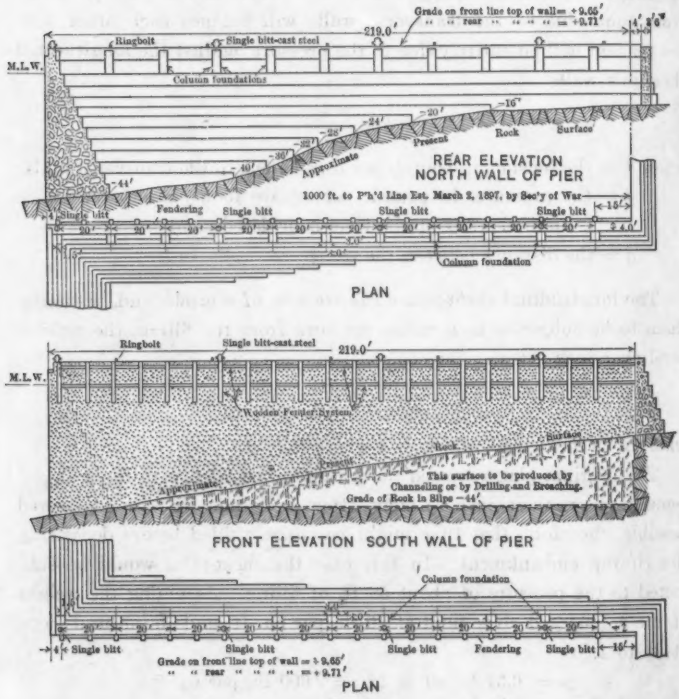

FIG. 5.

at the rear. These tests are incomplete, but, though it was found necessary to discontinue them, they are given here for whatever value may be derived from them.

The testing apparatus provided a bottom having the average slope of the rock floor at West 46th Street, 6 to 1, and also glass sides, 3 ft. apart, in order to observe the effect of pressures on the mass. The

board, against which the embankment was placed and by which the pressures were transmitted to the embankment, was fitted so as to slide inward on the bottom and between the glass sides. The embankment consisted of broken stone weighing as placed about 93 lb. per cu. ft., and varying from $\frac{1}{4}$ to $\frac{3}{4}$ in., which is about one-twentieth the size of rip-rap. The pressures were obtained by using two calibrated steel car springs, which were compressed by a nut working on a threaded bolt, passing partly through each spring, and fastened to the backing blocks attached to the base of the apparatus. The pressures applied were determined from the decrease in length of the springs, a gauge being used for each spring, giving the pressure directly in pounds.

In order to determine the behavior of the embankment under pressure, vertical lines were marked on the ground-glass sides, and along them columns of small wooden blocks were laid up in the embankment. These columns of blocks moved with the embankment, and the extent of their displacement from their original positions was measured as the pressure was increased. Figs. 6, 7, 8, and 9 are reproduced from photographs showing various views of this model.

Six tests were made with this model under different conditions, with the results shown by Figs. 11, 12, and 13.

In Test 1, the board transmitting the pressure extended the full height of the embankment, or 3 ft. 6 in. The embankment had a berm of 10 in., and the pressure was applied at one-third the height from the bottom.

In all the tests the embankment was 3 ft. 6 in. high, but, in all but Test 1, the board was only 33 in. high, being placed against the upper 33 in. of the embankment, the lower edge of the board being approximately in the horizontal plane through the toe. The pressure in Tests 2, 3, and 4 was applied at one-third the height of the board from its lower edge. Tests 5 and 6 will be referred to later.

The object of these tests was to determine the extent of the distortion which would take place in such an embankment under pressure, as well as its ultimate resistance.

Figs. 11 and 12 show the distortion throughout the mass in Tests 1 and 2, obtained by measurements of the displacement of the blocks of wood referred to. Also, the curves of deflection of the embankment with the increase of pressure are shown by Fig. 13.

In Test 1, at a pressure of about 2 375 lb., a tendency to break, about through the horizontal plane through the toe, was observed, and is indicated by the breaks in the lines in Fig. 11 at this pressure, as well as in the break in the curve of deflection shown in Fig. 13.

The pressure above the horizontal plane through the toe corresponding with 2 375 lb. on the whole board is 1 460 lb. The weight of the embankment above this plane is about 1 900 lb., and the corresponding value of μ is 0.77, as compared with 0.83 indicated by the natural slope of 1.2 to 1.

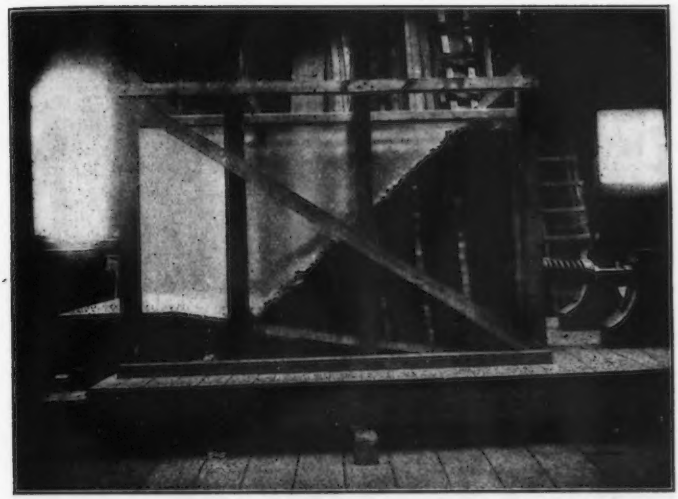
A second break occurs in the deflection curve in Fig. 13 at a pressure of 2 750 lb. Assuming this as an indication of sliding up the inclined bottom, taking the weight of the embankment at 2 380 lb., the tangent of the angle made by the bottom with the horizontal at $\frac{1}{4}$, and substituting those values in the formula,

$$\mu = \frac{P - \text{tan. } \alpha\ W}{W + \text{tan. } \alpha\ P},$$

we have a value for μ, the coefficient of friction of the stone on the wood bottom, $= 0.83$. This high value is presumed to be due to the probability of the stones becoming embedded in the wood to some extent.

Considering the break in the deflection curve for Test 2, Fig. 13, at 1 280 lb. as an indication of sliding along the horizontal plane through the lower edge of the pressure board, the weight of the embankment above this plane being about 1 750 lb., the resulting value of μ for broken stone on broken stone is 0.73. The critical pressure of 1 000 lb. in Test 3 gives a value for μ of 0.80. These values compare with 0.83 indicated by the natural slope of 1.2 to 1.

The movement of the embankment in these tests, accompanying each increase of pressure, would apparently cease in a very short time. The readings of both pressures and movement were then taken, and the next increase of pressure effected. It became evident, however, that, particularly for the higher pressures, further movement will occur when more time is allowed. This is illustrated in Test 2, Fig. 12, under pressure 8, in which case the pressure against the embankment dropped from 1 805 to 1 565 lb. over night, accompanied by a corresponding movement of the embankment. To determine the effect of time, Test 4 was made on an embankment similar to that used in



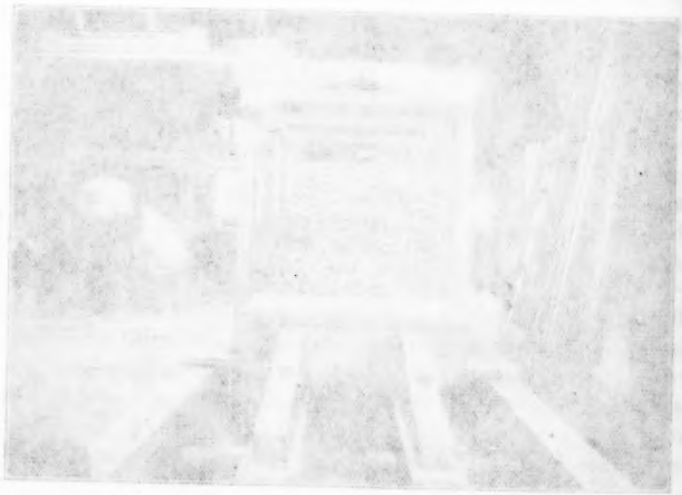


FIG. 6.—SIDE VIEW OF MODEL, SHOWING DISPLACEMENT OF COLUMNS OF WOODEN BLOCKS AT END OF TEST 1, WHEN THE PRESSURE AGAINST THE EMBANKMENT HAD REACHED 2 810 LB. THE BLACK VERTICAL LINES SHOW THE ORIGINAL POSITION OF THE COLUMNS OF WOODEN BLOCKS.

FIG. 10.

Test 2, with a berm of 10 in. The springs were compressed until they indicated a pressure of 1 060 lb. The accompanying movement of the embankment at the top was 0.07 in. At the end of 1 week, the springs indicated a pressure of 950 lb., and this drop in pressure was accompanied by an additional movement of 0.045 in. at the top of the embankment. At the end of 1 month, the pressure had dropped to 900 lb., with a further displacement of the embankment at the top of 0.08 in. Observation of the embankment at the end of the second month indicated no further change either in pressure or displacement.

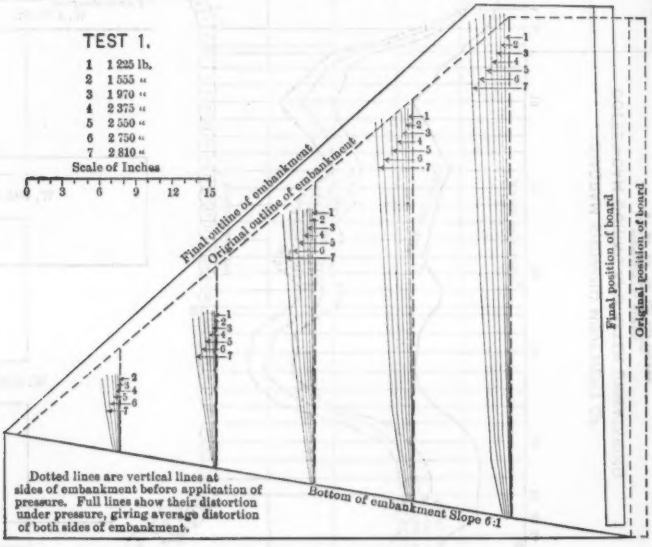

FIG. 11.

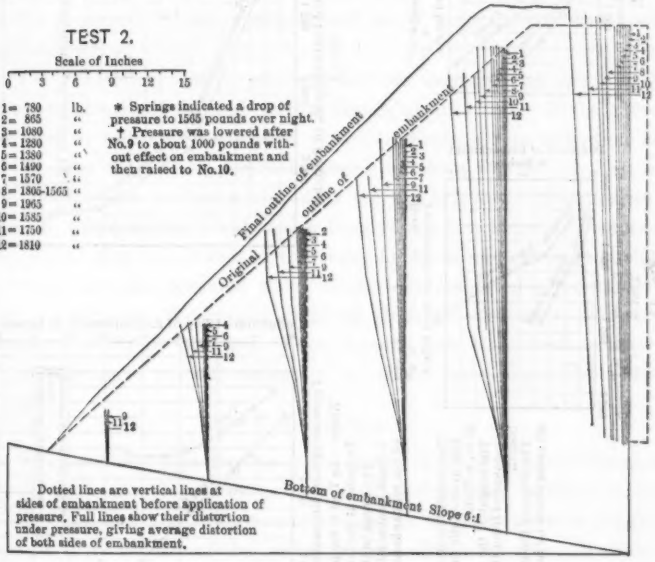
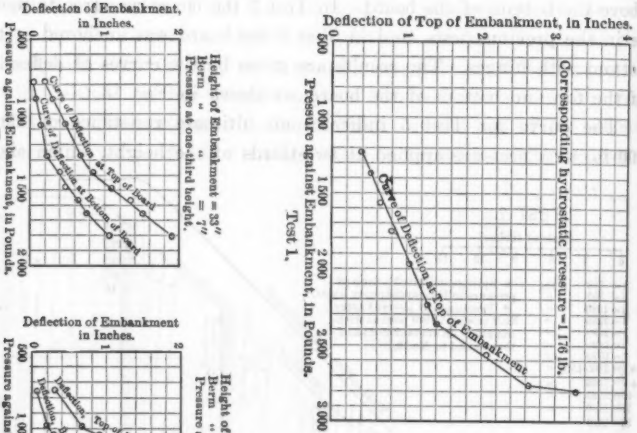
This test does not show that the embankment would not have come to rest in time under a pressure greater than 900 lb. constantly applied, which could not be determined with the apparatus used, as any movement of the embankment necessarily results in a partial release of the springs, and consequently a decrease in pressure.

Tests 5 and 6 were undertaken to determine the effect of applying the pressure at a point above the center of gravity of the embankment as well as the effect of friction along the face of the embankment in contact with the board.

The embankment used in these tests was the same as that in Test 2, except that the width of the berm was about 6 in. In the case of Tests 5 and 6, the pressure was applied at two-thirds of the height above the bottom of the board. In Test 5 the board was free to move, as in the previous tests, and in Test 6 the board was anchored at the bottom with hinges. The results are given by the curves of deflection of the top and bottom of the board, as shown in Fig. 13.

The curve for Test 5 indicates an ultimate resistance of about 600 lb. to a pressure applied at two-thirds of the height, which about





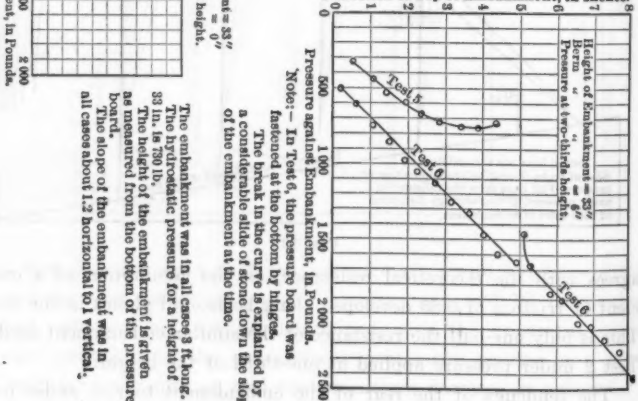


FIG. 12.

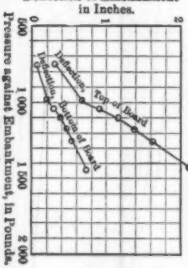
agrees with the theoretical resistance, on the assumption of a coefficient of friction of 0.83 developed along horizontal planes in the mass. This is only one-half the resistance of the similar embankment used in Test 2 under pressure applied at one-third of the height.



The tendency of the rear of the embankment to rise under pressure, carrying the board with it, was very evident in Tests 1, 2, and 3. In Tests 5 and 6 the movement was entirely horizontal. To determine the effect of friction between the board and the face of the embankment, the board, in Test 6, was anchored as mentioned pre-

Test 1.

Note:— In Test 6, the pressure board was fastened at the bottom by hinges. The break in the curve is explained by a considerable slide of stone down the slope of the embankment at the time.

Test 2.

Test 3.

The embankment was in all cases 3 ft. long. The hydrostatic pressure for a height of 33 in. is 730 lb.

The height of the embankment is given as measured from the bottom of the pressure board.

The slope of the embankment was in all cases about 1.3 horizontal to 1 vertical.

FIG. 13.

viously. The result is shown by the lower curve, Fig. 13. Considering the resistance developed along horizontal planes in the embankment, and assuming a value of 0.83 for the coefficient of friction for both stone on stone and stone on wood, the ultimate resistance in this case should be about 2 500 lb. Under the maximum pressure developed in this test (2 400 lb.), no indication of failure was evident. The excessive deflection of the embankment made it impracticable to carry this test further. The friction along the face in contact with the board would evidently be more effective the lower the point of application of the pressure. These results should be of value in the design of bulkhead walls.

The theoretical active pressure for the embankment in Test 1 would be about 280 lb., and that in Test 2, about 170 lb. If the curve for Test 1, Fig. 13, is extended, it will indicate a zero deflection at 800 lb., and for Test 2, a zero deflection at about 600 lb. In Test 4, the board rested against a wale near the top before the pressure was applied, a thin slab of wood having been placed between the board and this wale. Any movement of the embankment would release the slab of wood, and this occurred when the springs indicated a pressure of 850 lb., checking the results obtained from the deflection curve as closely as could be expected. These results seem to indicate a maximum resistance, without deflection, of about three times the active pressure.

Construction.

Pile-Driving.—The driving of the sheet-pile pockets in the designed shape was accomplished by driving four timber piles in the location for each pocket, and these served to support a plank templet slightly smaller than the size of the pocket, around which the steel piles were set. The piles of the first five pockets were set in such order that the closure occurred in the inshore panel, the remaining pockets being set so that the closure came in the diaphragm common to adjoining pockets, it being easier to get a good fit for the closure pile in the straight diaphragm than in the curved inner panel.

In setting the piles, their own weight caused them to settle in the mud to a depth of about 20 ft., so that they were required to be driven only about 10 ft. The driving was done with a "New Monarch" type of steam hammer, weighing about 4 000 lb., bolted to a frame which fitted over the piles and held the hammer in a vertical position, the

hammer plate being wide enough to drive three piles at once. After being driven in sets of three, the individual piles were driven with a follower, in order to insure contact of each with the rock. As the first five pockets were in the area formerly occupied by the inner end of the West 47th Street pier, a considerable quantity of timber was encountered, which made the setting and driving of the piles difficult. In the case of Pockets 3, 4, and 5, timber was encountered near the surface of the mud, which caused some of the piles to project so high when they were set that it was necessary to drive them with a steam hammer down to grade, which would allow the adjoining piles to be entered. This resulted in throwing Pockets 4 and 5 so far out of plumb that the piles adjoining the closure pile in each pocket were farther apart at the bottom than at the top. The hard driving necessary to draw these adjoining piles together caused the rupture of one jaw of the closure pile in Pocket 5, leaving a gap in the inner panel of about 25 ft. from the rock bottom. A similar condition was produced in placing the closure pile in the diaphragm between Pockets 8 and 9, it being impossible to detect the fact that the closure pile had passed out of the adjoining jaws.

There was no difficulty in driving the piles to rock between Pockets 8 and 35, the bottom having been dredged to 30 ft. below low water, removing practically all the timber usually found embedded in the upper surface of the mud.

At the beginning of the return at West 44th Street, however, a great deal of trouble was caused by the proximity of the two large cylindrical pockets to the inner end of the 44th Street pier. Before dredging was done at this point, a timber crib occupied a large part of the area covered by Pockets 35 and 36, extending under the inshore end of the pier shed. In dredging with a dipper-dredge it was impossible to clear out the bottom of the crib close to the shed on account of the danger of damaging the structure, consequently some of the piles in Pockets 36 and 35½ encountered the projecting ends of the round crib timbers. Very hard driving was required to put down the piles which were close to the crib, four piles in Pocket 35½ requiring 24 hours of driving with a 2-ton steam hammer. Apparently, these four piles passed through three courses of crib logs, as the very bad driving occurred in three stages, yet there were no indications that they were parting from each other or curling up, and they finally brought

up solidly on the rock. Evidently, however, there was a rupture, as practically all the leakage of the entire dam took place through the outshore side of Pocket 35½.

The setting of pockets, which was begun with No. 1, on April 10th, 1914, was continued until No. 27 was reached, on June 19th, 1914. Owing to a change in plan, setting was then suspended until October 5th, when it was resumed in No. 35, the cylindrical pocket, and carried thence to Pocket 44. Pockets 28 to 30 were then set, Nos. 31 to 33 being omitted until the lighter had completed the removal, from the rear of the dam, of all the mud which it could not reach from a position outside the dam. The lighter was then placed outside the dam and the remaining pockets were set, the closure being made in Pocket 31 in the middle of the inshore and outshore panels.

Dredging and Filling Pockets.—The weakness at these two points was soon developed when the filling of the pockets was begun. In the case of Pocket 5, the mud had been dredged from the inshore side to a depth of about 30 ft. below low water, the material being placed in the pocket to a grade of about 7 ft. above low water. There was thus a head of about 37 ft. of mud on the inner panel, which, after the lapse of a few hours, completed the opening of the gap at the closure pile.

In order to repair the damage it was necessary to remove some of the filling which had been placed in Pockets 6 and 7, and thus allow the corner pile between Pockets 5 and 6 to be pulled back into a vertical position. The distorted piles of the ruptured panel were removed and new piles were placed, two being added to the original number to fill the space caused by the spreading of the corners when the filling was suddenly released.

The failure of the diaphragm between Pockets 8 and 9 occurred when the filling in No. 8 had reached — 12, and in No. 9 when it had reached — 20, and the mud inshore from the two pockets had been dredged to about — 40 ft. The original plan, in constructing the dam, was to dredge the material in the rear overlying the rock, place it in the pockets, and then proceed to deposit rip-rap at the rear; and, when the rip-rap had reached the level of the mud, outshore from the dam, to deposit filling outshore in sufficient quantity to counteract the pressure of the rip-rap.

The failure of Pockets 5 and 8 made it evident that this procedure would have to be modified, unless there was assurance that the closure piles were not under considerable initial stress. A number of the closure piles had required considerable driving, and it was decided to avoid unduly stressing them by proceeding as follows: The mud in the rear of the dam was excavated for the length of two pockets and taken to sea; rip-rap was then deposited until it reached the grade of the original bottom in the pockets; filling was then placed in the pockets, and a head of mud and earth of about 10 ft. over the grade of the rip-rap was maintained as the placing of rip-rap was continued. Sufficient tension was thus maintained in the walls of the pocket to make them water-tight without subjecting them to severe loads. The filling comprised a mixture of mud and cellar earth, the latter being dumped from trucks which were driven along a platform built on top of the dam. As the earth was dumped in the middle of the pockets, its greater weight forced the mud up along the walls, providing a seal which proved to be absolutely water-tight.

During the time required for the foregoing operation of dredging and filling, which averaged about 10 days for each pocket, the unbalanced pressure of the mud in the pockets and also that outshore from the latter caused them to lean inshore. The mud in which the piles were set is of a stiff, clay-like consistency which will stand at a steep slope for a considerable time if undisturbed. The impact of the 2-yd. buckets of mud on the original filling in the pockets apparently was sufficient to destroy the cohesion in the mass, causing it to exert pressure tending to tip the pocket inshore. The maximum movement of a pocket (No. 16) immediately after the completion of the dredging was ½ ft. in 24 hours, and there was a maximum total movement of about 2½ ft. in the 10 days required to restore the balance of pressure on the sides of the pocket. The average movement during the time of placing the filling was about 1½ ft. The balance of pressure, once restored, was easily maintained by placing the earth embankment outshore to counteract the pressure of the rip-rap.

In dredging and filling the cylindrical pockets (Nos. 35 and 36) a different procedure was necessary, on account of the change in the type of construction. Whereas, in the small pockets, the pressure of the mud inside tended to hold them in the same shape as when they were set, in these cylinders, as it was necessary to clear the inside

FIG. 14.—LAYING OUT TEMPLATES FOR DRIVING SHEET-PILING.

FIG. 15.—SHEET-PILING FOR POCKETS DRIVEN.

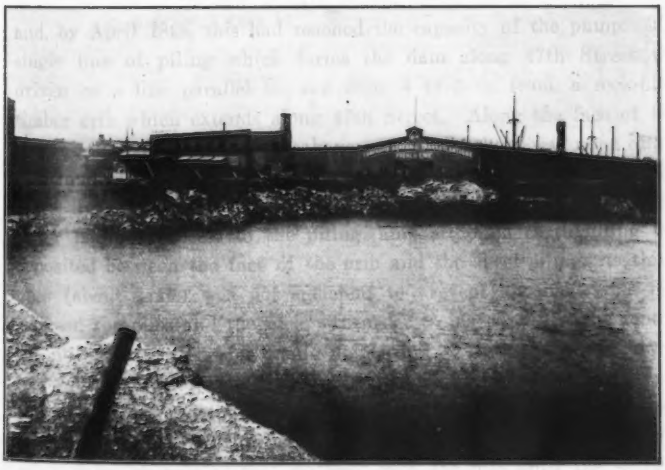

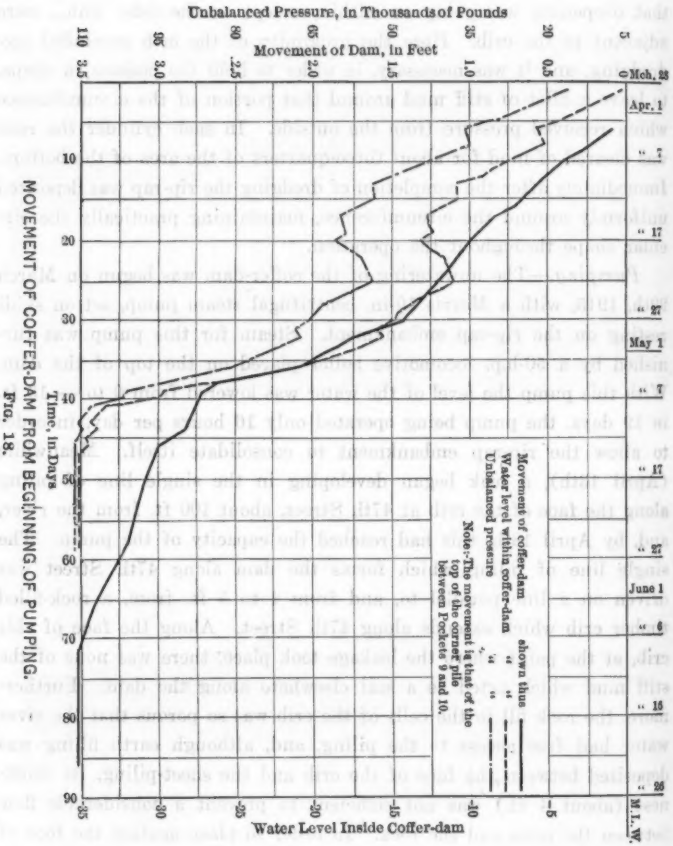

FIG. 17.—LARGE POCKET, AND RIP-RAP EMBANKMENT, WEST 44TH STREET.

of mud in order to bring the rip-rap in contact with the rock bottom, there was some danger that the pressure of the mud around the outside might distort or collapse the cylinders. This danger was avoided by dredging around the outside of the cylinders at the same time that deepening was going on within, except on the sides which were adjacent to the crib. Here the proximity of the crib precluded any dredging, and it was necessary, in order to hold the pockets in shape, to leave a fillet of stiff mud around that portion of the circumference which received pressure from the outside. In each cylinder the rock was cleared of mud for about three-quarters of the area of the bottom. Immediately after the completion of dredging the rip-rap was deposited uniformly around the circumference, maintaining practically the circular shape throughout the operation.

Pumping.—The unwatering of the coffer-dam was begun on March 29th, 1915, with a Morris 10-in. centrifugal steam pump, set on skids resting on the rip-rap embankment. Steam for this pump was furnished by a 50-h.p. locomotive boiler placed on the top of the dam. With this pump the level of the water was lowered from 0 to — 13 ft. in 19 days, the pump being operated only 16 hours per day, in order to allow the rip-rap embankment to consolidate itself. Meanwhile (April 13th), a leak began developing in the single line of piling along the face of the crib at 47th Street, about 100 ft. from the river, and, by April 18th, this had reached the capacity of the pump. The single line of piling which forms the dam along 47th Street was driven on a line parallel to, and from 4 to 5 ft. from, a rock-filled timber crib which extends along 47th Street. Along the face of this crib, at the point where the leakage took place, there was none of the stiff mud which acted as a seal elsewhere along the dam. Furthermore, the rock fill in the cells of the crib was so porous that the river water had free access to the piling, and, although earth filling was deposited between the face of the crib and the sheet-piling, its thickness (about 4 ft.) was not sufficient to prevent a considerable flow between the piles and the rock. In order to place against the foot of the piling material which would not be drawn through by the flow of water, wooden piles were driven at intervals of from 4 to 5 ft. between the steel piling and the face of the crib. These were then withdrawn, and the holes filled with a mixture of sand and horse manure by ramming down charges of this material with the pile until the stiffness

MOVEMENT OF COFFER-DAM FROM BEGINNING OF PUMPING.
FIG. 18.

of the driving indicated that the cavity was filled. By thus introducing material which would clog easily, and by consolidating the earth filling for about 50 ft. along the sheet-piling, the flow was reduced to small proportions.

During the 9 days required to stop this leak, the water level rose from — 13 to — 11 ft., although the 10-in. pump had been running for 24 hours per day for the last 4 days. On April 22d the level again began to recede, the pumping plant being supplemented on April 29th by two 6-in. and one 4-in. Alberger centrifugal pumps, electrically operated. These were on a raft within the coffer-dam. After setting up the electrically operated pumps they were run continuously, and the 10-in. steam pump was run for 16 hours per day. In 16 days (April 22d to May 8th) the water level was reduced from — 11 to — 34 ft., at which point the accumulated mud in the bottom of the area was exposed.

At about this time water began to flow through Pocket 35½, appearing at the bottom of the piles in the inshore panel. It was then discovered that the closure piles of this inshore panel had parted from the adjoining piles for several feet from the bottom, probably due to driving the panel in a curve of too small a radius. It appeared that the leak occurred in the outshore panel of Pocket 35½, where there was a possible rupture due to driving through the timber crib. The same method as used at 47th Street—of driving down manure to hold the earth filling—was applied along the outside of Pocket 35½, and, although the flow was reduced, it was impossible to cut it off entirely. Coincident with the removal of the mud in the bottom of the excavation, the water level was lowered until the final grade of — 44 ft. was reached. The three small pumps were removed, and a 12-in. Worthington centrifugal pump, electrically operated, was placed on the same platform as the 10-in. steam pump, on the rip-rap embankment at a point about 30 ft. below low water. The 12-in. pump was thenceforth used to keep the dam dry, the 10-in. pump being maintained as a reserve. The total inflow amounted to about 2 500 gal. per min., of which probably 2 000 gal. came through Pocket 35½, and the remainder from the cut-off along 47th Street and from the upland. There was no indication of any leakage whatever through the portion of the dam composed of the small cells, and it is evident that, had conditions permitted their use throughout, the leakage would have been slight.

During the progress of unwatering, daily observations of the movement of the dam were made, so that, if necessary, the rate of pumping might be changed in order to check undue movements, but the changes were at no time so great as to cause apprehension. The maximum inshore movement at any one point in 24 hours was 0.40 ft. at Pocket 25, when the water level was lowered from — 24 to — 27 ft.; and the total movement during the 40 days required to remove the water to — 34 ft. was 2½ ft. The dam continued to lean inshore after pumping had been completed to — 44 ft., with a slowly decreasing rate, coming practically to rest by June 15th, 1915. The total inshore movement of the top was about 3½ ft.

Fig. 10 shows the alignment of the coffer-dam for several stages of the unwatering, and Fig. 18 shows the history of the movement of a typical section of the coffer-dam as the unwatering proceeded. The unbalanced pressures were calculated on the assumption of a hydrostatic head from rock at the inner row of sheet-piles at — 60 to + 4.

Plant, and Rock Removal.

The plant provided for handling the excavated material and concrete comprised eight 15-ton steam locomotive cranes, of which six were used in the slip and pier areas and two on the old 45th Street pier. These narrow-gauge steam locomotives provided transport for concrete and spoil. The six cranes used in the coffer-dam were placed so that all parts of the area could be covered, three being carried on timber trestles extending inshore from the dam, the other three partly on trestles and partly on the two pier side-walls and the slip wall at 44th Street. There were two lines of narrow-gauge track along the top of the dam extending out on the old 45th Street pier, where the two cranes loaded the rock into scows lying alongside the pier. Spurs extended to the bulkhead along 47th Street and to the cranes on each trestle. There were also three stiff-leg derricks with 70-ft. booms, one at 47th Street, about 50 ft. outshore from the bulkhead wall, one at the north side of the pier, in the rear of the bulkhead wall, and one near 44th Street, at the bulkhead. These derricks were operated by compressed air, supplied by the plant provided for the rock drilling.

In placing the trestles for the locomotive cranes, a crane was set up on top of the dam, and the mud at the toe of the rip-rap embankment was excavated with a 1½-yd. "battleship" which operated some-

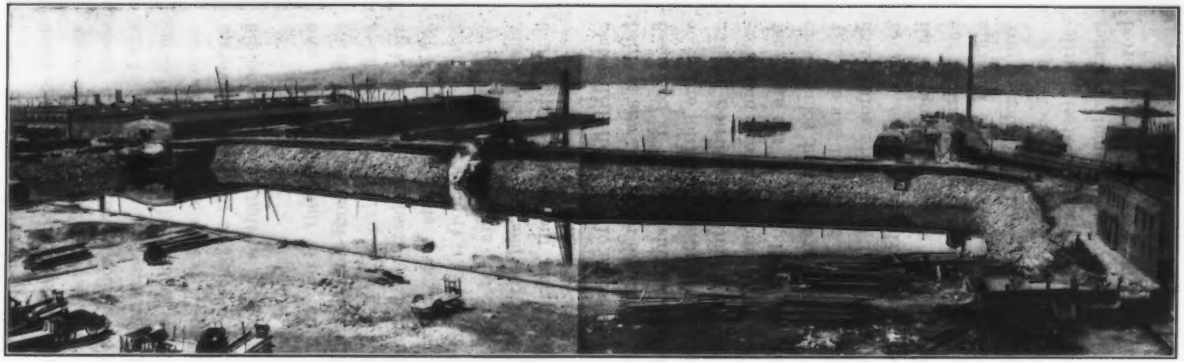

FIG. 19.—LEVEL OF WATER INSIDE COFFER-DAM, MAY 1ST, 1915, 17.9 FT.

FIG. 20.—CONCRETE CORNERS AND LOWER COURSE FOR RETAINING WALL, SEPTEMBER 10TH, 1915.

what after the manner of a clam-shell bucket. As the toe of the slope was beyond the reach of the crane boom, several 24-in. I-beams were laid on the rip-rap, and the bucket was allowed to slide down them. After the rock had been uncovered, a trestle bent was erected at the foot of the bank, and an intermediate bent half-way up the slope. These bents were spanned by five 24-in. I-beams on which the crane track was laid. Successive bents were erected as the rock excavation proceeded, the trestles finally being extended so that the cranes would reach the bulkhead.

The rock excavation was begun at the toe of the rip-rap bank, and carried thence toward the bulkhead. Ingersoll-Rand tripod air drills were used until the depth of the cut was about 22 ft., and then Cyclone well-drilling machines, operated by gasoline engines, were substituted. The small drill holes, which were started with a 3½-in. and finished with a 1½-in. bit, were about 4 ft. from center to center. The well drill holes were 6 in. in diameter, and were about 14 ft. from center to center. Along the line of the pier and bulkhead walls, line drilling was done with the tripod drills, the holes being from 6 to 8 in. apart.

There was considerable difficulty with some of the small drill work, on account of the seamy nature of a part of the rock; this was avoided by the use of the well drills. The rock in this locality is composed of hard gray granite and Manhattan schist, with little order or arrangement in their occurrence. In the outshore portion of the excavation, the rock proved to be a fine, sound granite, which furnished a good foundation for the pier side-walls, but, in the area east of a line about 75 ft. from the bulkhead, granite and schist were encountered in irregular layers. The strata of the schist stood nearly on edge, as is usual, and varied from a hard to a quite soft, much laminated, structure. The granite, particularly within the area of the bulkhead wall, was badly broken up by seams, running in all directions and mostly filled with mud. In a number of locations the rock was of such poor character that it was necessary to excavate within the wall area, down to the grade of — 44 ft., in order to provide proper support for the front of the wall.

The rock was disposed of by loading it by hand into steel "battleships" and wooden skips, which were hoisted by the locomotive cranes to flat cars of about 3 cu. yd. capacity. These cars were transported

by locomotive to the pier at West 45th Street in trains of from six to eight cars, and there unloaded by two locomotive cranes into bottom-dumper and deck scows. The rock thus loaded was shipped to Riverside Park, between West 88th and West 95th Streets, and there deposited along the shore in a trench, so as to form an embankment for the extension of Riverside Park. Other portions of the rock excavated were used for back-filling in the rear of the pier and bulkhead walls, and for the cyclopean concrete.

Pier and Slip Walls.

The plant for the concrete work was erected on a pile platform, about 30 ft. wide and 100 ft. long, built adjoining the outshore side of the dam near the 47th Street end. On the platform there was a cement shed with a capacity of 4 000 bags. A 1-yd. Ransome mixer, electrically operated, was placed at an elevation which allowed it to discharge into buckets set on flat cars on the track running along the top of the dam. Hoppers for stone and sand, of 90 and 45 cu. yd. capacity, respectively, were erected directly over the mixer, resting partly on the dam and partly on the platform. A timber stiff-leg derrick, with a 70-ft. boom, operated by compressed air, and set at the same elevation as the hoppers, supplied them with sand and stone from scows moored alongside, using a 1½-yd. clam-shell bucket. The cement was elevated to the charging hopper by a chain bag conveyor run by an electric motor. For use in cold weather, steam pipes were inserted in the sand and stone hoppers and in the mixing water tank. In operation, a flat car with two bottom-dumping buckets, each holding a batch, was run under the discharge chute of the mixer by a locomotive, whence it was transported to the locomotive cranes which placed the concrete in the forms.

In the construction of the slip walls, the rock on the foundation was thoroughly cleaned of all loose and rotten pieces, washed with a stream of water, and given a coat of mortar. The concrete was brought up in steps of 4 ft. and bonded together by allowing the derrick stone placed in it to project from one course into the other. Steel forms, in sections of 5 by 10 ft., were used, except for the face of the wall for the top 14 ft. Here a wooden form was used, in order to produce a better surface and to facilitate the placing of anchor bolts for the fender system. All the pier and bulkhead walls were built in sections 30 ft. long, each section being tarred to provide an expansion joint.

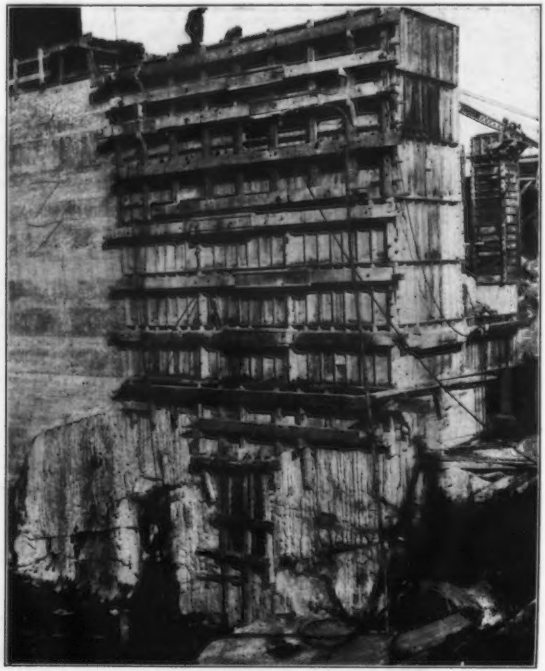

FIG. 24.—SIDE FACE OF SOUTH PIER WALL, SHOWING COMPLETED CONCRETE, LINE-DRILLED ROCK FACE, AND WALL FORMS ABOVE, NOVEMBER 6TH, 1915.

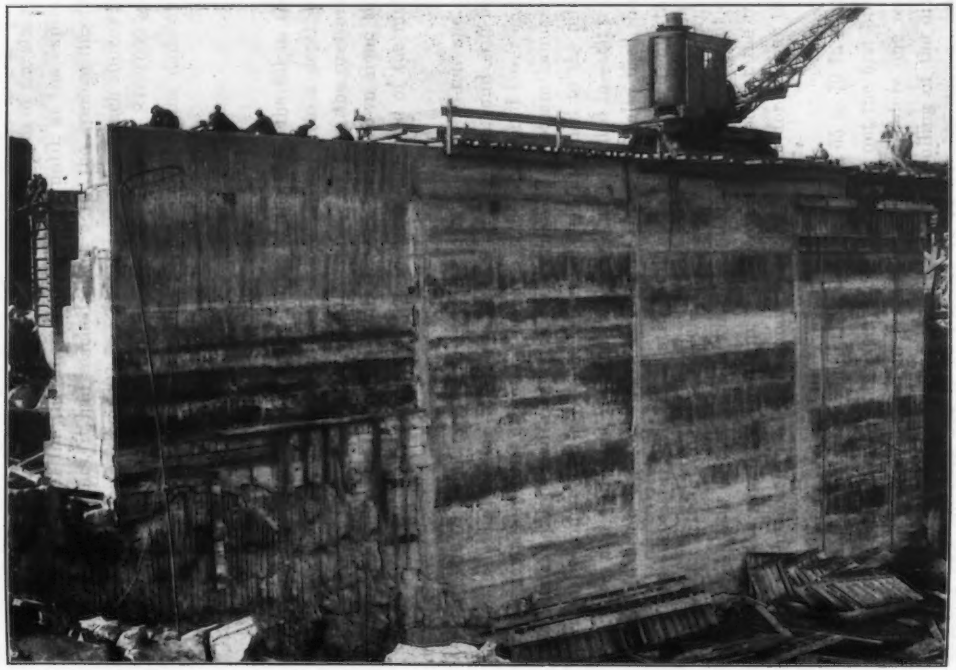

FIG. 25.—ROCK FACE AND CONCRETE RETAINING WALL, NORTH SIDE OF PIER, NOVEMBER 6TH, 1915.

Rewatering.

The rewatering of the coffer-dam was effected on June 29th, 1916, by opening the sluice-gates when the tide was at about the low-water stage, which gave a head of 1 ft. of water over the bottom of the sluiceways. The rising of the tide increased the head until, at the expiration of about 6 hours, it had reached about 5 ft., the average during the rise of the tide thus being 3 ft. The clear width of each sluiceway was 7 ft. 8 in. To fill the dam to its capacity of about 8 000 000 cu. ft., 8 hours were required. Practically no movement of the dam was caused by the rewatering.

Removal of the Coffer-Dam.

Preliminary to pulling the sheet-piling of the dam, the fill in the pockets and in the outshore embankment was removed to a depth of about 10 ft. below low water, in order to relieve some of the pressure, and jet pipes, operated by compressed air, were forced down along the piling nearly their full depth, in order to break the hold of the mud on the piles.

The plant for pulling the sheet-piling comprised a 25-ton and a 40-ton steam lighter for the main portion of the dam, and stiff-leg derricks for the returns extending inshore at the upper and lower ends of the dam, equipped with inverted McKiernan-Terry steam hammers operated by compressed air. The hammers were attached to the piles with 3, 3½, and 4-in. pins, inserted in a single hole burned in each pile about 2 ft. below the top. Various types of grips were also used, but the most successful was a relatively light one furnished by the Lackawanna Steel Company, which was rigged so that it could be opened by pulling a trailing rope when the pile had been pulled out of reach from the ground. This grip, which catches the pile at the top of the web, has been used continuously by one lighter for all but the hardest pulling.

The pulling was started where the piles were from 65 to 70 ft. long, and considerable difficulty was experienced in taking out the first pile, about a week being consumed in trying various piles before one was extracted from the diaphragm of Pocket 28. The pulling of the diaphragms and outshore panels of Pockets 18 to 29 was then accomplished by driving them up with the hammer.

It was found impossible, however, to start any of the piles next to the rip-rap embankment by these means. A 100-ton lighter was

secured with the intention of using it, with an inverted hammer, to break one of the inside arcs. After working 4 days and trying several pockets, this rig, being unable to budge any of these inside piles, was dispensed with. A heavy, guyed, A-frame was then erected on top of the rip-rap embankment and rigged with a set of eight-sheave blocks, with sixteen parts of $\frac{7}{8}$-in. line, through which the pull of the 25-ton derrick was transmitted to the pile. A 64-ft. pile was thus drawn by direct pull without the aid of the hammer. The line of piles adjacent to the rip-rap having thus been broken, no further difficulty was experienced in this direction, and the remaining piles were drawn by the derrick aided by the steam hammer.

As a rule, all the piles came out straight and in a condition satisfactory for use in other work.

After the removal of the sheet-piling, the filling, outshore earth embankment, and inshore rip-rap embankment will be removed by dredging.

Cost of Work.

Dredging.—The dredging was executed under two separate contracts, first for the original contract, and then over the area of the supplementary contract. Under the first contract, 271 882 cu. yd. were removed, at a cost of 23½ cents per cu. yd. Under the supplementary contract, 87 875 cu. yd. were removed, at a cost of 27 cents per cu. yd., making a total, for the removal of material by dredging down to solid rock, of $87 618.52.

Coffer-dam, Rock Excavation, Walls, etc.—After due advertisement of the specifications and plans, based on an engineer's estimate of $497 000, for the coffer-dam and walls of the pier, the Department obtained thirteen bids, ranging from $750 000 to $487 000, the low bid, which was awarded to Holbrook, Cabot and Rollins, Incorporated.

In order that the work might be extended southward to West 44th Street, to comprise an area which it was not possible to include at the time of the original preparation of the contract, a supplementary contract was entered into with the same contractors at the same unit prices, after receiving permission from the Board of Estimate and Apportionment and the Board of Aldermen to extend the work in this manner.

It was clearly demonstrated at that time that a saving of fully $150 000 would be made by doing the work in connection with the

original coffer-dam, thereby avoiding the cost of building a new coffer-dam at the south end of the work.

The total of the original and supplementary contracts for the work of building the coffer-dam, excavating the rock, and constructing the concrete walls for the inner part of the pier building, was $626 000.

The unit price for the removal of solid rock under the contract was only $1.60 per cu. yd., but assuming that one-half the cost of the coffer-dam should be charged against rock excavation and the other half against the construction of the concrete walls and other items within the coffer-dam, the actual cost for the removal of this solid rock, was about $5.31 per cu. yd.

Conclusion.

First.—Instead of excavating this large quantity of subaqueous rock by the "dry" method, the work might have been performed without a coffer-dam by the ordinary method of rock blasting under water, or, in other words, the excavation of the rock "wet".

If it were possible to perform this work so as to obtain under water vertical face walls to the exact limits of the slip, it would have cost, under ordinary normal prices for this class of work, four or five times as much as by the method adopted.

It is not possible to conceive, however, that the work could have been done under water, for, as a matter of fact, it was very difficult to do it with line drilling in the open, and further, even were it possible to deposit concrete in a satisfactory manner at such depths, part of the work in addition would have been very expensive.

The particular result obtained by the construction of this dam was that, although all preliminary examinations, borings, soundings, etc., were made when the whole territory was covered by filling of all kinds, including, in places, cribwork, coal yards covered with coal, buildings, etc., the total amount paid under the contract obtained through unit prices has been kept close to the original estimates.

Second.—The whole river face of this dam, for a length of about 800 ft., under its full water head, was absolutely dry, all the pumping, during the whole construction period having been done by one 12-in. centrifugal pump. Furthermore, all this pumping would have been avoided, although much more was expected, had it not been for the presence of cribwork at the north side, and on account of the impossi-

bility of driving two piles in the large cylinders at the south end, because, in driving, a boulder or some other interference was encountered, rendering it impossible to drive these two piles home for a distance of only about 1 ft.

SUPERVISION.

The work was executed by the Department of Docks and Ferries, R. A. C. Smith, Commissioner of Docks, and R. C. Harrison, First Deputy Commissioner.

The design, preparation of plans and specifications, and the construction was under the direction of the writer, as Chief Engineer, assisted by R. T. Betts, M. Am. Soc. C. E., Deputy Chief Engineer; Mr. T. F. Keller and Elias Cahn, Assoc. M. Am. Soc. C. E., Assistant Engineers. The work in the field was under the direction of J. J. Pemoff, M. Am. Soc. C. E., Assistant Engineer.

The contracting firm for the work was Holbrook, Cabot and Rollins, Incorporated.

Acknowledgment is made by the writer of the skill and perseverance of the contractors, particularly of T. B. Bryson, Assoc. M. Am. Soc. C. E., on the work. The writer's thanks are also due to Brig.-Gen. William M. Black, M. Am. Soc. C. E., Chief of Engineers, U. S. A., for advice in the preparation of the plans, and the support of his assurance that this work could be accomplished successfully provided proper construction methods were used.

DISCUSSION

Mr. Harris

FREDERIC R. HARRIS,* M. AM. SOC. C. E. (by letter).—The author has presented his subject so clearly and fully that extended comment is unnecessary.

On first reviewing the paper one is impressed particularly with the large sum of money involved for the construction of only 220 ft. of pier and the excavation of areas adjacent to the pier sufficient for three slips. However, when it is considered that it was necessary to limit the projection of the pier outshore, it will be realized that the sum expended for the inshore construction was not exorbitant. It must also be taken into account that the greater part of the steel sheet-piling was salvaged and was available, therefore, for use on other work.

In coffer-dam construction, as in other constructions of this class, the unknown element confronts the engineer. Officers of the Corps of Civil Engineers of the Navy have been forcibly impressed with the hazards accompanying construction of this class, as there is little room for doubt that most of the delays and failures in naval dry dock construction are traceable to weak or faulty coffer-dam construction. When both the design and construction of a coffer-dam are imposed entirely on the contractor, there is a strong temptation to save on first cost and perhaps to take chances on additional and unnecessary risk. The contractor is seldom to blame for this condition, as he is often forced into an untenable position by the double competition involved, first, in competitive bids in which his estimated cost of the coffer-dam which he plans is a part; and, second, in which the saving that he may believe he can make on the coffer-dam determines his profit, or, worse still, a decrease in his loss.

The writer has been much interested in the construction work described, having discussed it quite frequently with Mr. Staniford, Messrs. Holbrook and Bryson, of the Holbrook, Cabot and Rollins Company, and the Commissioner of Docks and Ferries, Mr. R. A. C. Smith, and has been influenced largely by Mr. Staniford's able and conservative engineering plans, as shown by this work, to depart from the precedent heretofore established in the plans and specifications for naval dry docks. This departure, although it has not taken the exact form of designing the coffer-dam required for the work, has, nevertheless, laid down and specified a minimum coffer-dam requirement that would be acceptable to this extent, attempting, as Mr. Staniford did in the work described, to minimize the risk and safeguard against the probability of failure, with its attending losses of money and time.

* Washington, D. C.

Mr. Harris. The fact that the coffer-dam described by the author held and served most satisfactorily the purpose for which it was constructed, is evidence of the soundness of the judgment used in its design.

The writer is particularly interested in the tests made to secure information on the behavior of the rip-rap embankment under various conditions of pressure. The following are the results of computations made from the data in the paper:

In Test No. 1, assuming the head to be 3 ft. 6 in., the active pressure was found to be 360 lb.; the pressure at impending motion, 1 455 lb.; and actual sliding on the bottom 2 800 lb., assuming the same coefficient of friction on the bottom as that of the material itself, and no friction on the board to which the force is applied. These assumptions may account for the figures given being slightly larger than those obtained in the test.

In Test No. 2, the head assumed was 2 ft. 9 in. The computed active pressure found was 250 lb.; the computed impending motion, 970 lb.; and for sliding, 1 460 lb., assuming a plane of rupture through the toe and no friction on the board to which the force is applied.

In Test No. 5, the head was assumed to be 1½ times the distance of the application of the force from the top. At impending motion, the computed force was found to be 500 lb. and the sliding on the plane through the toe to be 680 lb.

From observations of the curves shown in Fig. 13, it is believed that the initial movement was probably purely local, and that the impending motion began at the initial points of the curves shown. The agreement of the computations with the critical points of the curves is remarkable, and partly verifies such an assumption.

Mr Watt. D. A. WATT,* M. AM. SOC. C. E. (by letter).—It would be of interest to know whether any piles were found, during the removal of the pockets, which had been driven out of their interlock with the next piles. In the writer's experience, this is by no means uncommon where the driving is hard, for instance, with closing piles, although no indication of the break may be apparent at the time. Thus, when removing the coffer-dam for the *Maine* at Havana, more than one case was found where one pile at one-quarter or one-third of its length from the end had broken away from its neighbor. Fortunately, the breaks were all below the level of the harbor bottom, which doubtless was the reason the cylinders had not burst, as the surrounding material (mud and clay) prevented the embedded piling from spreading. The piles had been driven from 30 to 35 ft. into this material. During the construction of the coffer-dam one of the cylinders broke open, due to the closing pile being driven out of the interlock, but in this

* Albany, N. Y.

case the weak point appeared to be above the harbor bottom, where there was no outside material to counteract the strain. Mr. Watt.

Similar conditions were found in the later steel-pile-pocket coffer-dam at Troy, N. Y., where the piles were driven into river gravel. The penetration was not more than 8 or 9 ft., as the gravel was compact; yet, when removing the piling, several cases were found where the interlock had driven out. As with the *Maine* coffer-dam, the breaks appeared to be below the surface of the bottom, and no harm resulted.

The saturation of the filling in coffer-dams of this type, referred to by the author as one of the sources of internal pressures, appears to exist at a higher level than is usually assumed, although varying naturally with the porosity of the filling. The filling used for the *Maine* cylinders varied from a sandy to a heavy clay, and in all cases the saturation line was very high. It began at about mean tide level on the outer faces and sloped downward at about 5 horizontal to 1 vertical. The material, therefore, was dry only to an average of about 5 ft. below mean tide; the remainder stayed in a fluid condition. Efforts to lower the saturation level and to drain the filling with long perforated pipes were useless; the pipes would fill up in a few hours after being pumped out, and even near the surface these did not seem to affect visibly the adjacent seepage. This high and constant line of saturation was noteworthy because the total seepage into the coffer-dam was extremely small (about $\frac{1}{2}$ cu. ft. per sec.), and there was as much opportunity for the water to leak out of the cylinders into the inclosure as to leak into them from the bay. In the Troy coffer-dam, with the pockets filled with sand and gravel, the water line was naturally much steeper. Judging from the height of the seepage appearing on the inside faces, it was about 2 horizontal to 1 vertical.

The writer visited the 46th Street coffer-dam during its construction, and again after it had been in use for some months. Mr. Staniford and the others responsible for the work are to be congratulated on their success in handling a very difficult problem.

C. A. WENTWORTH,* M. AM. SOC. C. E.—The Society has received a valuable contribution in this paper, describing an advanced step in coffer-dam construction to meet peculiar and difficult conditions. The tests made in preparing for this work show a foresight which is too often omitted. A comparatively small expenditure for borings and tests at the outset of a difficult piece of foundation work frequently saves much larger expenditures later. The entire responsibility of determining the method to be used in carrying out a given design is too often left entirely to the contractor, instead of considering the method and final structure desired as parts of the same construction, both of which are essential to a completed whole. Mr. Wentworth.

* Wayne, Pa.

Mr. Wentworth.

The relative amount of yielding in the rip-rap embankment of the large coffer-dam confirms the results of the small-scale tests remarkably well, and the description in the paper gives all the points necessary for use in applying this method to similar work. The difficulties encountered in the construction were surprisingly small, considering the magnitude of the work; and there is evidence of careful preparation in laying out and carrying on the work which is a credit to both the engineers and the contractor.

A coffer-dam of the open type, without cross-bracing, must fulfill two functions: First, it must provide a cut-off wall sufficiently tight to hold back the water and prevent it from opening channels, through or under the dam, which might endanger its stability or cause a seepage flow which could not be cared for by the pumps with reasonable expense. This does not mean that an absolutely tight cut-off is necessary, and, in fact, a water-tight cut-off is seldom obtained. It does mean, however, that large leaks or seepage must be stopped.

The second function which a dam must fulfill is to provide sufficient stability to resist the total pressure of the water. This stability depends on two factors: The total mass, and the internal cohesion of the mass, or its resistance to deformation. In the coffer-dam under discussion, the cut-off consisted of a double row of steel sheet-piles, interlocked and driven to rock, and sealed with a clayey mud. This cut-off was ideal as a stop for percolating water. The rip-rap furnished —in the most compact form of any loose material—the necessary mass, with the maximum stability attainable, short of a coherent structure.

In this case there was a coffer-dam requiring a cut-off wall 68 ft. in height. Engineers must expect to encounter these problems more frequently in the future, and the methods used must meet the conditions. The methods applicable in any given case should be governed by local conditions and the cost of available material. When this work was started, 2 years ago, the cost of steel piling was low, and contractors were seeking places for the cheap disposal of rip-rap from the subway excavations. These two factors undoubtedly had much to do with the type of coffer-dam selected. A third factor which defined the limits of the work was the rock bottom, which made an unyielding support, both for the steel cut-off wall and the rock fill. A variation of any one of these three factors, such as a high cost for the first two or a different character of bottom, might have made some other type advisable. Each of these factors should be given its true weight in considering the use of similar construction in other work.

If the same work were to be done again, with the present high price of steel, and rip-rap being more expensive, some other means might well be considered, such as the use of open concrete caissons sunk by the dredging method and weighted by filling with mud, or

timber caissons similarly sunk and weighted. These two types would represent coherent structures in which the minimum quantity of material is required to resist the pressure, and their use in this or any other case would be entirely a question of relative costs. Mr. Wentworth.

Another dam which should be considered is the ordinary timber sheet-pile and earth-fill type. Such a dam would necessarily have to be placed a greater distance from the bottom of the excavation in order to provide room for the greater mass and flatter slopes required, and also to provide a longer distance for the travel of seepage which might pass a cut-off wall not carried to rock. The latter method would not meet the restricted conditions at the north and south sides of the coffer-dam under discussion, and, in fact, the general method of construction was varied at these points to suit local conditions, large circular caissons being used at the southwest corner, and a single line of sheeting along part of the north side.

These alternates are pointed out in order to call attention to methods which might well be considered in connection with a similar problem under different local conditions.

The paper suggests some thoughts which may not be out of place in this discussion. Harbor development in the United States is now at a point where new methods and types of construction will be required to meet the increased draft of ocean vessels, and to provide for a greater permanence in the design of docks and bulkheads than has prevailed in the past. Timber has been cheap and of excellent quality, and has served its purpose well, for coffer-dam and dock work, for depths of water up to about 30 ft.

Most of the docks in the United States are built of timber, usually untreated. The life of work of this class is short, unless entirely submerged in waters free from marine worms, but it has had the advantage of cheapness and rapid construction, and these have been the deciding factors in a rapidly growing and changing community. In the teredo-infested waters of southern and Pacific ports, creosoted timber and other forms of protection have been a necessity for wooden piles, and, even with such protection, the increased cost and decreased life of dock structures built of this material have made the need of more permanent materials desirable.

For permanent docks in depths of 40 ft. or more, which are now required for the largest ocean vessels, timber is getting beyond its reasonable limit, and the use of concrete or masonry walls or piers, or supporting dock structures by concrete caissons, will probably be the next step forward to meet these new conditions of permanency and depth. These methods are suitable, not only in waters where the teredo is not found, but also for most conditions encountered where a permanent dock is required.

Mr. Wentworth.

Concrete piles have been used in many places infested by the teredo, but they cannot be considered as permanent in waters subjected to ice and frost action, and their permanency in tropical waters is questionable, due to the greater chemical activity of the dissolved alkaline salts in the warm water and the great rapidity with which the steel reinforcement disintegrates when the necessarily thin protecting layer of concrete is broken or punctured.

No engineering work is immutable, and permanency, when applied to harbor work, can only be considered as relative; but it is evident that a new era has been reached in constructing works of this kind, especially in ports like New York. It is a pleasure, therefore, to see the substantial design of the dock walls constructed inside the coffer-dam for the 46th Street Pier, and it is hoped that this work may be a precedent for future construction.

Mr. Wiggin.

THOMAS H. WIGGIN,* M. AM. SOC. C. E.—The author very modestly calls this an unusual coffer-dam. A stronger term might very properly have been used, as will be agreed to, the speaker thinks, by any one who has had experience with such work. The construction itself, after the coffer-dam was completed, and even the methods of building the coffer-dam, were not in themselves so bold, because, though requiring great skill and ingenuity on account of unusual dimensions, they involved methods of pile-driving and excavation which are sufficiently well standardized; but the conception of backing so high and so large a coffer-dam with a mass of rip-rap of comparatively small thickness was certainly one which required boldness, care, study, and sureness, in order to warrant a construction, in that limited space, which did not give opportunity for increasing the strength of the backing, in case it should be found insufficient.

It seems to the speaker that the experiments undertaken to discover the action such a structure might take, deserve more emphasis than the author gives them. They were, apparently, the only quantitative proof of the design. The speaker made a few rough computations, and would be interested if the author would include an outline of such computations as were made by him to justify the proportions of the design. For example, the prism of rock which supported the steel walls on the side next the river, appears to have had a weight of about 200 000 lb. per lin. ft., and the water pressure against it appears to have been approximately 100 000 lb. This would indicate the necessity for a coefficient of friction of about 50% in order that the rock fill should withstand successfully the inward pressure when the coffer-dam was unwatered. The experiments appear to show that the coefficient of friction at the ultimate strength of such a "granular" structure, when subject to sliding pressure, would be considerably greater than 50%, perhaps half again as large.

* New York City.

Mr. Wiggin.

The margin, then, was apparently safe, but not large, and the considerable movement of the structure indicated that just about the right degree of conservatism was used in the proportioning. If the structure had been a little lighter, it might have exhibited signs of distress as the water was lowered inside, and, as there was little more room for additional rip-rap inside, a determination of the next step would have been a serious problem. No such distress occurred, however, and the design was justified, which must have been a source of great gratification to the author and his assistants, and is reason for admiration by the Engineering Profession.

The paper leaves little to be added, though its descriptions are given with a minimum of words. There are a few points, however, which might be explained in more detail. The first is the use of wash-borings and steel-shod piles for the purpose of finding the position of bed-rock. Under many circumstances, neither of those methods would have been reliable. The speaker knows of areas where rock has been located in great detail by wash-borings, but, on excavating, no rock was found; and, similarly, with the driving of rods or piles, it is difficult to know that one does not strike boulders. The speaker presumes that the Dock Department was familiar with the general nature of the shore, and felt confidence in the methods; otherwise, that a few borings of another sort, that is, diamond drill or core borings, would have been made in order to be sure that certain critical points were well established.

It is noted that along the north side of the coffer-dam a single row of steel sheet-piling was used. Of course, two rows give more certainty of cut-off than one, but it would be interesting to have Mr. Staniford explain whether a single row would not have done elsewhere. The principal stability appears to have been derived from the rock fill inside the steel piling, and it would seem to be possible to use a single row and back it up so well with rip-rap as to make the cellular construction unnecessary. The speaker visited the work several times during construction, and noted particularly that the cells of the steel piles along the south line were very much distorted by the pressure. They were no longer cells, for some of them were convexed toward the interior of the coffer-dam on both sides; that is, they had simply been forced over by the action of the outside fill so that they constituted not a row of cells, but two rows of piling with certain cross-diaphragms. Considering the amount at stake, the speaker is not at all surprised that two rows, or even more, should have been thought desirable as a factor of safety; but, after the experience, the point of view as to whether one row would be sufficient for the future would be of interest.

Mr. Wiggin.

It is noted that the steel piling manufacturers have established a strength of about 9 500 lb. per lin. in. for the interlock. This is an important unit to remember in connection with such steel piling, because it has been well established by tests, all giving substantially the same figure, and it will be possible, in many cases, to use such piling locked together as a sort of suspension for supporting pressures.

There are a few places in the paper where the derivation of certain formulas, or, at least, a reference to their derivation, would add to the completeness; for example, on page 505, there is a factor of 57% which presumably comes from the Rankine sine formula for active pressure. The formula on page 508, for coefficient of friction, would be clearer for some explanation.

In one or two places, also, references to slopes are ambiguous, such as a slope of 1.2 to 1, or 3 to 1. The wording leaves doubt as to whether the horizontal is the larger or the lesser figure in the ratio.

In connection with this paper, mention might be made of some steel piling work which the Board of Water Supply did on Staten Island. The Narrows siphon is a 36-in., flexible-jointed, cast-iron pipe, laid across the Narrows, from Brooklyn to Staten Island. On the Staten Island shore, it had to be laid below the level of the bottom of a future dock, and as the material for that dock had not been excavated, it was necessary to carry a trench for a length of about 250 ft. through a firm sandy material varying in depth from about 10 ft. at the toe up to about 50 ft. near the shore, the maximum depth obtaining for some distance. This pipe was laid under water, so that it was not necessary to unwater the excavation, which, therefore, was not a coffer-dam, but merely a sheeted trench with earth and water outside and water alone inside.

The first design considered was the use of interlocking steel piles, laid in straight lines, with wooden rangers and cross-bracing. That, undoubtedly, would have been successful, but it would have required the placing by a diver of a good many pieces of timber for the rangers, posts, and braces.

It was finally proposed to sheet the trench with interlocking steel piles driven in arcs festooned between steel master-piles. The sheet-piles carried the load as a suspension in a horizontal plane between the master-piles, which were held apart by wooden braces. This design differed from that first described in substituting suspension systems for wooden rangers, an arrangement which incidentally eliminated the bearing across grain of braces on rangers, which is a source of weakness.

The sheet-piles were supplied by the U. S. Steel Company, and were 12½-in. and 38 lb. per yd. The so-called master-piles were spaced about 15 ft. apart along the trench; each consisted of a 12-in., 50-lb., I-beam, with a 12½-in. sheet-pile riveted to one flange and a 12-in., 25-lb. channel to the other, to give it additional strength.

Mr. Wiggin.

Many of these sheet- and master-piles were about 65 ft. long. The arcs of festoons were 15 ft. in radius, which, under the assumptions of earth pressure, caused a theoretical tension in these curves of about 3 000 lb. per lin. in., as compared with 9 500 lb., which was the supposed strength of the interlock.

There was difficulty, as was expected, in driving the master-piles exactly plumb and in correct position through the firm material. After they were down, each one was carefully surveyed by locating two points on it at the top as far apart vertically as practicable, and then projecting the line of these points to the position at the bottom. An investigation was then made as to what curvature would really result, making due allowance for the bending of the piles and inaccuracies in the location measurements, and wherever the curvature to be expected was less than about one-half that which was tried for originally, another sheet-pile was put in the arc, thus increasing the middle ordinate of the curve and reducing the stress.

Mr. Thomson.

T. Kennard Thomson,* M. Am. Soc. C. E.—Mr. Staniford deserves the thanks and congratulations of the Engineering Profession for the marvelously successful solution of a most difficult engineering problem. Commissioner Smith also deserves the thanks of every one in New York City and State, as well as of many outside these limits, for his courage, ingenuity, and success in securing for Manhattan the 1 000-ft. docks for which there is such urgent demand.

The author's experiments are very interesting; but, as a rule, it is almost impossible to make such experiments really conclusive, on account of the great difficulty of allowing for all the conditions of Nature. For instance, in a small model, a pile representing a rock fill dumped into place would probably have a considerably smaller percentage of voids than in the actual work, and some of these voids might occur in such a way that the subsequent breaking of a few stones might cause a sudden slide, with injurious results, especially if the stones are coated with slime, which condition, also, could not be obtained in the model. Then, again, the formation of ice might be disastrous, although difficult to make allowance for in the experiment.

A coffer-dam or retaining wall, supporting a fill, built of such proportions as to be absolutely safe under most conditions, will fail completely under a load of semi-liquid material of the same weight and height, due to the fact that it will act as a sort of ram. It is always very difficult to estimate the effect of water on a fill, during or after construction, as the cumulative effect is much greater in some materials than the hydraulic head would indicate.

* New York City.

Mr. Thomson.

In sub-surface work or excavations, it is even much more difficult to estimate the real pressures on a coffer-dam or retaining wall. The materials have been placed, for the most part, by Nature, under great pressures; and are often cemented together by clay or other natural cements, and by roots, stones, etc., so that considerable excavation can often be made without any coffer-dam or bracing. These conditions cannot be reproduced in ordinary experiments, and, in actual work, are often suddenly reversed by the action of springs, rains, etc.

Any experiments, therefore, which are intended to reduce the sections of retaining walls, dams, or coffer-dams below the standards adopted as the result of many experiments, theories, and actual examples, should be checked with the utmost care and foresight.

The author refers to the use of manure for stopping leaks. A very simple expedient, often used successfully in coffer-dam work, where the leaks are small but persistent and troublesome, is to drop an occasional shovelful of ashes or cinders in the water above the leak. This would probably also remedy many leaks in concrete and masonry dams and thus prevent much serious damage from ice forming in the cracks and crevices.

Although too much credit cannot be given to Commissioner Smith and Mr. Staniford for conceiving and constructing this greatly needed improvement, one cannot help comparing it with a surgical operation, for instance, for appendicitis. Both are expensive, and both are absolutely necessary. In this case it was necessary to remove 12 acres of valuable New York City real estate to make place for water.

The number of times such a surgical operation as the removal of the appendix (or city real estate) can occur is limited, of course, as far as the individual man or place is concerned, yet Manhattan needs many more 1 000-ft. docks—in fact, all that can be obtained—but the upper Hudson is not the most accessible place for them.

Six years ago, the speaker was much impressed with the wisdom of the War Department in refusing to allow further encroachment in the Hudson River, in spite of the very urgent need for such docks; he has always felt that there is a correct solution for all problems, if one only has the patience and ingenuity to find it.

In this case, when extension to the west was forbidden, and to the north and east was impossible, the only direction left was the south, it occurred to him that an extension might be made from the Battery to Governor's Island. Such a course, however, would obviously only accentuate a bad condition, for the City is too long and too narrow as it is. Later, the idea occurred to him that the City might be extended from the Battery 4 miles down the bay, with a width of about ¾ mile, and that a series of tunnels to Staten Island might

then be constructed. The City Hall would then be in the center of the city, instead of at its southern end. Mr. Thomson.

The next step would be to form a new bay between Staten Island and Sandy Hook, and introduce many other improvements, with which most engineers are familiar. The net result of this plan would be 50 sq. miles of new real estate and 100 miles of additional water-front. Some 6 or 7 sq. miles could be used for a free port between Staten Island and Sandy Hook. This, alone, an eminent banker has declared, would prove to be the salvation of New York.

Hamburg had to evict 16 000 people, as well as place drastic restrictions on many miles of river front; and even Bremen and Copenhagen were much restricted in their efforts to secure enough water and land space for their invaluable free ports. New York, however, can obtain all the land required without interfering with any one's interests.

CHARLES S. BOARDMAN,* M. AM. SOC. C. E.—The speaker wishes to call especial attention to the design of this coffer-dam. Mr. Staniford claims that a precedent for the design is found in the coffer-dams built by the United States Government at Black Rock Harbor, Buffalo, N. Y., and for removing the wreck of the battleship *Maine*, at Havana, Cuba. This is entirely true as to many details, such as the use of long steel sheet-piling, especially in the *Maine* coffer-dam, for the material in which each was constructed was harbor silt below about 35 ft. of salt water. The foundation of the *Maine* coffer-dam was in clay, but the steel sheet-piling for the 46th Street Pier was driven to bed-rock. It is true, also, in comparing the Black Rock coffer-dam, when it is considered that in that structure the steel sheet-piling was driven to bed-rock, although through good sand, clay, and gravel. Both the Black Rock and *Maine* coffer-dams differ in so many other details that neither can be considered a precedent for the design of the coffer-dam for the 46th Street Pier, New York City. Mr. Boardman.

Steel sheet-piling has been used in cellular-form, gravity-type coffer-dams, at Black Rock, Havana, Cape Fear River (Browns Landing), N. C., and Troy, N. Y., but never before as a cellular-type cut-off wall in a gravity-type earth and stone coffer-dam.

The form of the cell or pocket used by Mr. Staniford—with straight partition walls and curved longitudinal walls—has been developed from experience obtained at Black Rock and at Havana. It may be of interest, therefore, to follow this thought more in detail, giving a brief history of these two coffer-dams.

Mr. Staniford states:

"It was expected that the filling within the pockets [at Black Rock and Havana] would make them stable against the external pres-

* Buffalo, N. Y.

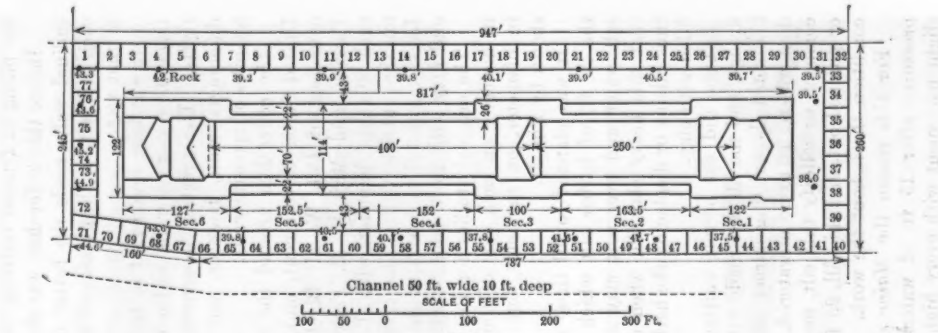
Mr. Boardman.

sures, unaided, but in both cases it was found necessary to place an embankment of stone against the pockets, and in the case of Havana, extensive bracing to the *Maine* was also placed, in order to stop the continuous inward movement of the coffer-dam."

This statement is correct, but the stone embankment was placed in each case for an entirely different reason than in the 46th Street Pier, where it forms part of the original design of the coffer-dam. This detail will also be referred to in a brief history of these coffer-dams.

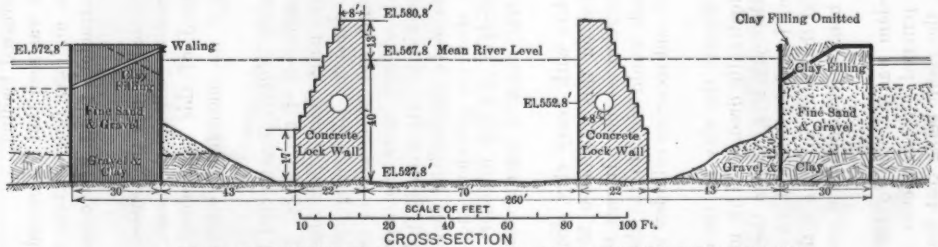
The Black Rock coffer-dam (Fig. 26) was constructed in 1908 and 1909, and consisted of seventy-seven pockets, each 30 ft. square, formed of Lackawanna steel sheet-piling, in lengths ranging from 41 to 54 ft. and driven in straight walls. All the piling was driven to bed-rock, making an average of 33 ft. of penetration through hard materials. The maximum penetration was about 45 ft., at the extreme west wall. Fig. 27 is a view, looking south, showing Pocket No. 40, the northeast corner in the foreground. In the background may be seen the City of Buffalo, the Niagara River, and the International Bridge. This photograph gives a general idea of the location of the ship lock in relation to the river.

The excavation was done by a dipper-dredge having an arm capable of digging to about Elevation — 45 ft., leaving from 3 to 6 ft. of clay and sand over the bed-rock.



The slopes of the materials forming the embankment by this dredging method were not maintained as prescribed in the Government engineer's plans, and, to re-establish these slopes, rock obtained from other work on the ship canal was placed by dump scows at the toe of the embankment and spread over its top by a dipper-dredge. This rip-rap was placed on the side embankments, but not on the end embankments of the coffer-dam, as will be seen in Fig. 28.

This figure also shows the elimination of the fill at the tops of the pockets against the inside steel walls, which would have formed an active pressure wedge against this wall. Fig. 29 shows the effect produced on the steel sheet-piling wall by the clay filling in the pockets when the embankment is low.



It is readily seen that this piling was thrown into tension at the joints. The maximum curvature of the wall was at a point one-third above the point of penetration, or the top of the embankment, the middle ordinate of these walls at this point being about 3 ft., or about one-tenth of the length of the pocket.

Later, during construction at this end coffer-dam, the toe of the embankment was robbed, causing a slide in the embankment, thus lowering the point of support of the piling. This also created a curved surface of rupture in the fill of the pockets. The steel sheet-piling

Mr. Boardman.

PLAN

CROSS-SECTION

PLAN AND CROSS-SECTION OF BLACK ROCK COFFER-DAM AND LOCK

FIG. 26.

Mr. Boardman.

being deflected further, the result was that the maximum deflection was at a point one-third of the height from the new point of support. The steel channels broke in many of the pockets, the interlocks of the piling in tension resisting this increased loading.

Before this coffer-dam was closed it was seen that the curved longitudinal walls made the better design, and the four pockets, two at each end, left for the passage of the contractor's plant, were constructed in that way.

It was then found that in the fabricated tee-pile the tension strain from these curved walls had a tendency to pull on the heads of the rivets. The greatest movement inward of this coffer-dam at the diaphragm walls, however, was only $\frac{3}{4}$ in., measuring between the tee-piles of opposite walls.

The coffer-dam around the battleship *Maine*, constructed by the United States Government, under supervision of the "Maine Board", composed of Col. W. M. Black (now Brig.-Gen.), Col. Mason M. Patrick, and Maj. H. B. Ferguson, consisted of twenty cylinders, each 50 ft. in diameter, with closing and connecting arcs of ten piles on the outside wall. The cylinders and arcs were constructed of Lackawanna $12\frac{3}{4}$ by $\frac{3}{8}$-in. straight-web sections, forty with 35-ft. lengths and fifty with 25-ft. lengths, spliced to make sheet-piling 75 ft. long.

The original studies for this work show six cylinders, each 50 ft. in diameter on each side of the coffer-dam and five cylinders, 40 ft. in diameter, on the ends, but this was changed later to the plan shown by Fig. 31.

It was planned to fill these cylinders with heavy clay, displacing the 25 ft. of harbor silt which existed on this site below 35 ft. of salt water and over soft clay at Elevation — 60. It was thought that this heavy clay fill, when dropped, would sink to the clay bed, thus raising or displacing the harbor silt and securing cylinders entirely filled with clay.

Time did not permit waiting to deposit the clay by the dipper-dredge, and the fill was made with a hydraulic dredge. This material blanketed the existing harbor silt in the cylinders. When the coffer-dam was ready to be unwatered, it was found impracticable to settle, compact, or solidify this silt, nor could the water in it be withdrawn or pumped out, and this fill, 25 ft. in height, remained in a semi-fluid condition throughout the work.

For this reason the *Maine* coffer-dam was affected by the water pressures after 15 ft. of water was pumped out, and even showed slight movement with every high tide, the result being that the cylinders gradually crept inward at the top, deflecting at Elevation 40 ft. or more below the water level, or where this harbor silt existed as fill in the cylinders. As the cylinders crept inward, the length of the center

FIG. 27.—BLACK ROCK COFFER-DAM, LOOKING SOUTH. POCKET NO. 40, THE NORTHWEST CORNER, IN THE FOREGROUND.

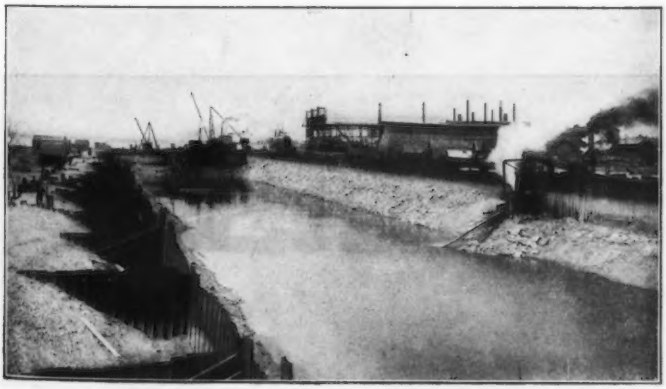


FIG. 28.—BLACK ROCK COFFER-DAM, LOOKING NORTH FROM SOUTHWEST CORNER. WATER 29 FT. BELOW NORMAL LEVEL OF NIAGARA RIVER.

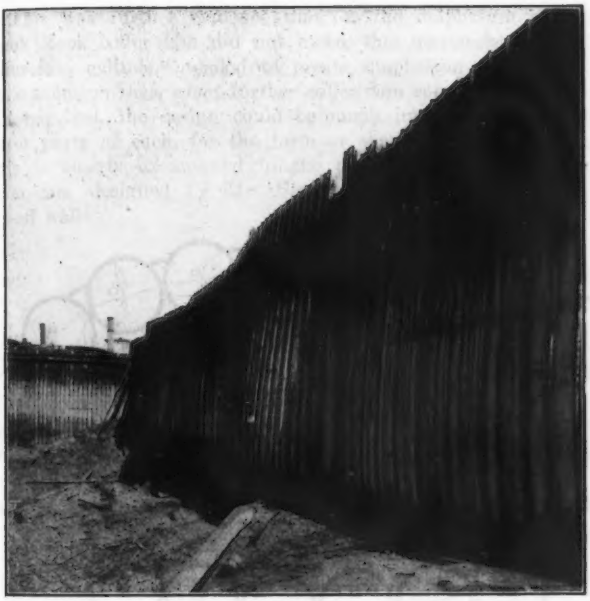

FIG. 29.—BLACK ROCK COFFER-DAM. INSIDE WALL AT SOUTH END. CLAY PUDDLE MOVING PILING TO THE LIMIT OF PLAY IN INTERLOCK.

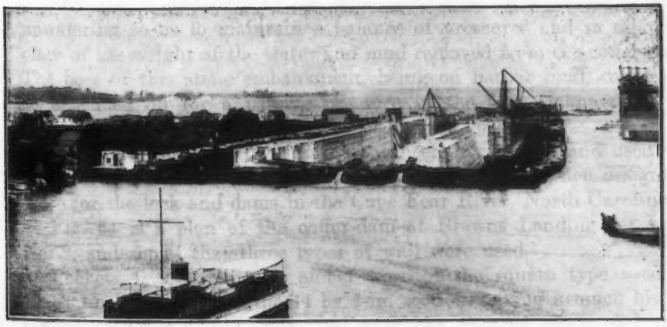

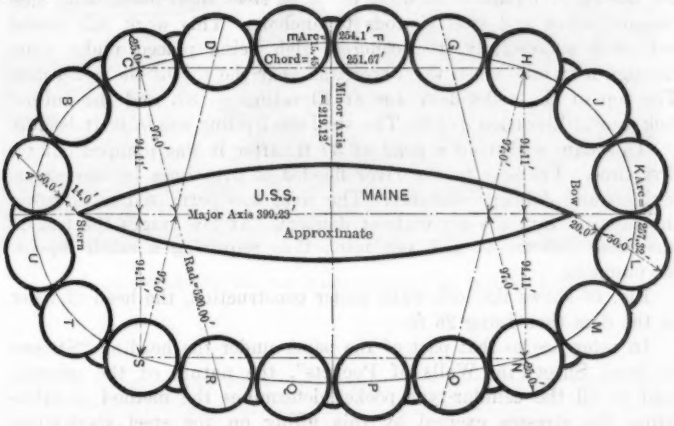

FIG. 30.—GENERAL VIEW OF BLACK ROCK COFFER-DAM, LOOKING NORTH, AT COMPLETION OF CONCRETE LOCK WALLS.

line of each became shorter, and they took an elliptical form, the area of contact between them increasing. Mr. Boardman.

This was further evidence that, as the diaphragm walls in the Black Rock coffer-dam did not move, this movement of the *Maine* coffer-dam cylinders tended to create diaphragm walls, and led to the conclusion that, when further coffer-dam construction of this type was required, the design could be much improved by adopting the better parts of each, for the form or shape of the cells or pockets. This is clearly exemplified in the plans for the 46th Street Pier coffer-dam designed by Mr. Staniford as steel sheet-pile cellular cut-off walls.

COFFER-DAM AROUND WRECK OF BATTLESHIP MAINE

FIG. 31.

The stone embankment of this coffer-dam was placed during unwatering so as to maintain a balance of pressures and to take the place of the weight of the water and mud removed from the coffer-dam. The base of this stone embankment, being on harbor mud, could not be depended on for a passive pressure in the same manner as the stone embankment for the 46th Street Pier coffer-dam.

The United States Government engineers recognized and used the best features of the Black Rock and *Maine* coffer-dams when designing those for the lock and dams in the Cape Fear River, North Carolina.

Fig. 34 is a plan of the coffer-dam at Browns Landing for Lock No. 2, and shows that three types of wall were used.

Pockets 1, 2, 3, 4, 5, 6, and 7 were of the square type used at Black Rock, except that the 14 by $\frac{3}{8}$-in. section, having a much higher section modulus (7.61), was used with the channel wales and steel rods across the pockets, in order to maintain their form.

Mr. Boardman.

Fig. 35 shows this coffer-dam during construction. The river walls were driven with two floating pile-drivers. A "pilot" pile of pine was driven at the corner of each pocket to support the template used in driving the curved walls.

Pockets 8 to 29, inclusive, but excluding Panel 21, were of a compromise design, these walls being driven on the shore of the river in the original ground. The back wall was driven with the 14-in. arch-web section, and the partition and front walls with the 12¾-in. straight-web section, the steel in the front wall being in tension.

Panels 21 and 30 each consist of a single wall, constructed after the design of bulkhead or dock walls, of steel sheet-piling with steel channel wales and steel tie-rods to anchors. This work was carried out most successfully, the concrete slab being placed under water through a tremie, when the water was near the top of the coffer-dam. The top of the coffer-dam was at Elevation + 32, and the finished lock floor at Elevation + 1.0. The steel sheet-piling was in 49-ft. lengths.

This dam withstood a head of 30 ft. after it was pumped out the first time. Freshets in the river flooded it five times in one season, without any damage whatever. The river was permitted to flow over the top and into the pit without damage. At low stages the leakage was from 200 to 500 gal. per min., thus requiring a small expense for pumping.

Fig. 36 shows the lock walls under construction, the head of water on the dam then being 26 ft.

In reference to that part of the paper under the heading "Stresses in Steel Sheet-Pile Walls of Pockets", the nature of the material used to fill the cellular-type pocket determines the method of calculating the stresses exerted by this filling on the steel sheet-piling walls. This pressure is transferred to the walls of the steel sheet-piling, and the walls are held intact by the strength of the interlock of this sheet-piling in tension. In 1908—previous to the construction of the Black Rock coffer-dam—the various interlocks of steel sheet-piling were tested physically for this value in tension per linear inch of interlock, and it was established that the Lackawanna steel sheet-piling developed an ultimate strength of 9 700 lb. per lin. in., which was then thought to be sufficiently high to allow such piling to be used for any depth then thought practicable for cellular pockets in a coffer-dam. The maximum stress developed by filling the pockets of the Black Rock coffer-dam, and to be resisted by the interlocks of the steel sheet-piling, was computed for the contractors by J. C. Meem, M. Am. Soc. C. E., and found to be 5 600 lb. per lin. in. of interlock.

Several articles were written by engineers on the stress that would be developed in the interlocks of the piling caused by the filling in

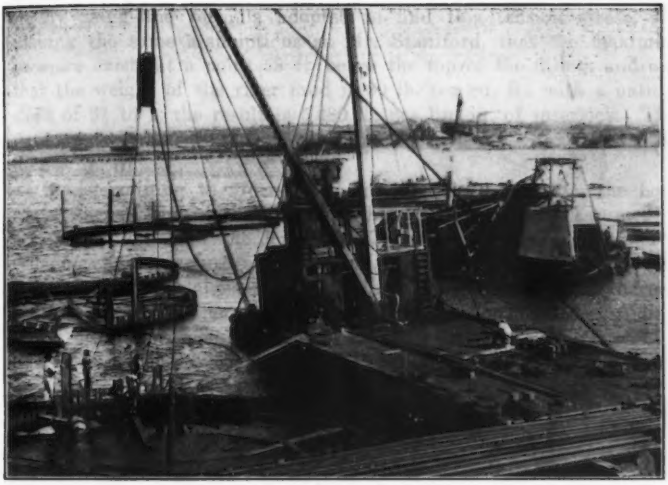

FIG. 32.—CONSTRUCTING THE *Maine* COFFER-DAM, HAVANA, CUBA.

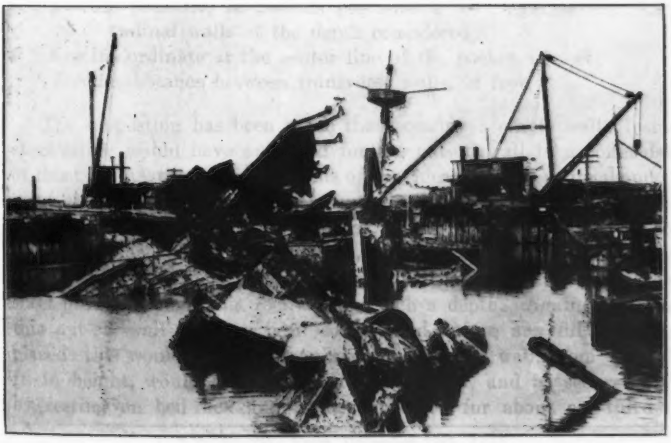

FIG. 33.—THE BOW OF THE *Maine*, WITHIN THE COFFER-DAM.
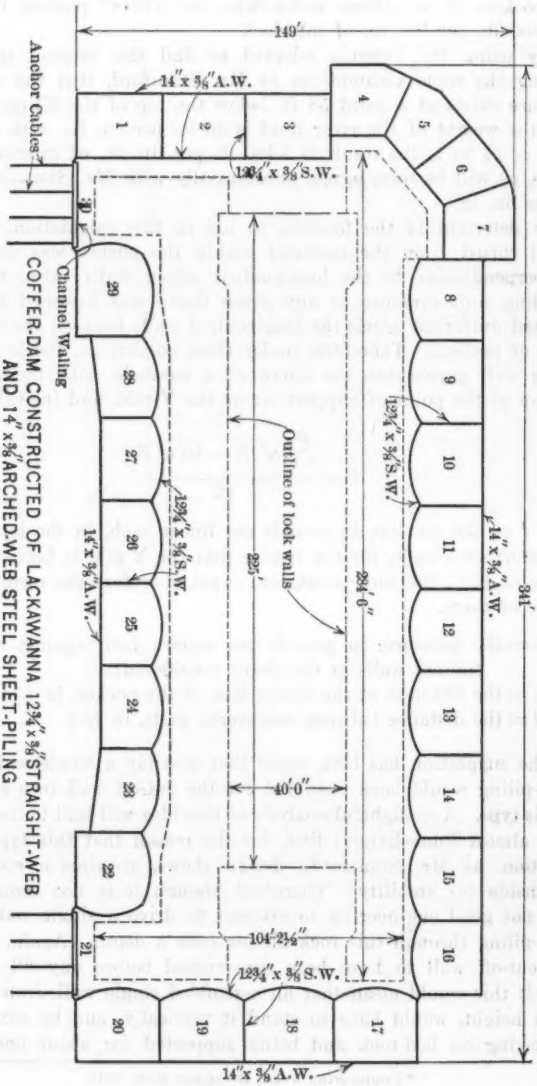
WATER AT ELEVATION — 10 FEET.

the pockets of the *Maine* coffer-dam, one writer* placing it as high as 7 400 lb. per lin. in. of interlock. Mr. Boardman.

By using the formula adopted to find this tension stress, and making the same assumptions as Mr. Staniford, that the maximum pressure exists at a point 58 ft. below the top of the filling, and also that the weight of the river mud is 80 lb. per cu. ft., with a natural slope of 3½ to 1, the result is 5 480 lb. per lin. in. of interlock. This figure, as will be seen, agrees substantially with Mr. Staniford's 5 200 lb. per lin. in.

In determining the formula to use in this calculation, the horizontal thrust from the material within the pocket was assumed to act perpendicular to the longitudinal piling walls; also, the corresponding unit pressure at any given depth was assumed to be distributed uniformly along the longitudinal walls between the transverse walls of pockets. Therefore, under these conditions, the longitudinal piling wall approaches the curve of a parabola with the maximum tension at the point of support, or at the Y-pile, and its value is

$$t = \frac{\frac{p}{8\,h}\sqrt{l^4 - 16\,h^2\,l^2}}{12}$$



when t = the tension, in pounds per linear inch, in the longitudinal and transverse walls, for the reason that the Y-pile is fabricated with angles of 120°, the components are equal, therefore the result is equal to one of them.

p = the pressure, in pounds per square foot, against the longitudinal walls at the depth considered;
h = the ordinate at the center line of the pocket, in feet;
l = the distance between transverse walls, in feet.

The suggestion has been made that possibly a single wall of steel sheet-piling would have answered for the cut-off wall in a coffer-dam of this type. A thoughtful analysis of this idea will lead to its abandonment almost immediately; first, for the reason that this type of construction, as Mr. Staniford's design shows, requires a rock fill on the inside for stability. Therefore, though it is not impracticable, it is not good engineering to attempt to drive a single wall of steel sheet-piling through this rock fill for such a depth. Again, assuming this cut-off wall to have been constructed before any fill had been placed: this would mean that an assembled single wall, from 60 to 70 ft. in height, would have to stand it vertically, and be secured only by resting on bed-rock and being supported for about one-third of

* *Engineering News*, December 29th, 1910.

Mr. Boardman.

COFFER-DAM CONSTRUCTED OF LACKAWANNA 12¾″ x ⅜″ STRAIGHT-WEB AND 14″ x ⅜″ ARCHED-WEB STEEL SHEET-PILING

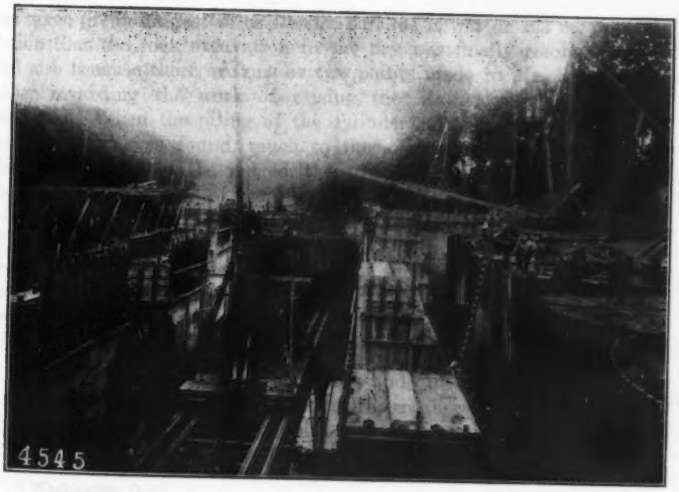

FIG. 36.—COFFER-DAM AT BROWNS LANDING. LOCK WALLS UNDER CONSTRUCTION.

its height in harbor silt. Any one who has assembled a wall of this kind, without first establishing secure supports for it, knows the difficulty in this kind of construction. To support such a single wall of piling until the rock fill could be made on the inside of the coffer-dam and the clay or rock fill on the river side, would require a temporary construction of timber, which would make the cost of establishing this timber support exceed the cost of building the cellular type of cut-off wall as adopted by Mr. Staniford, which, as has been proved, had sufficient base so that it was stable within itself during the filling of the pockets and during construction. It is readily seen that a cut-off wall of cellular type filled with harbor silt is absolutely watertight, and must have an advantage in this respect over a single wall of steel sheet-piling. Mr. Boardman.

The conditions at the 46th Street Pier, when thoroughly analyzed, show that the bed-rock sloped toward the river and had a very uneven surface, with little clay overlying it, and with harbor silt above it; and that this silt was the only available fill for the pockets. These conditions, and also the extreme depth of the coffer-dam, lead to the belief that Mr. Staniford adopted the best plan for this construction. The remarkable rapidity of its construction and the phenomenal success of the entire coffer-dam are proof positive that this is true.

WILLIAM M. BLACK,* M. AM. SOC. C. E. (by letter).—The writer has taken great interest in this coffer-dam, as it was on his recommendation that the rock excavation in the dry was finally resolved upon, and also because there are one or two points made in Mr. Staniford's paper regarding the work of raising the *Maine*, which should be corrected. When the piling of the cylinders of the *Maine* coffer-dam was drawn, it was found, much to the surprise of those in charge, that, as well as could be judged, there had been, in general, no movement of the lower ends of the piles forming the cylinder elements. In general, no movement of the lower end of the piling could be observed at all, but, in one or two of the cylinders, it is believed that some of the piles forming the inside elements of some of the cylinders might have been driven farther down into the clay by the cylinder movements. In general, the movement was a bending of the cylinders without affecting the level of the base. Mr. Black.

F. E. CUDWORTH,† ESQ.—The author and others have discussed the larger aspects of this improvement; the speaker will mention some of the smaller things connected with the work, and will take up a few of the problems which arose in carrying out the practical details of Mr. Cudworth.

* Washington, D. C.
† New York City.

Mr. Cudworth.

the ordering, transporting, handling, setting, and driving, and finally pulling the steel sheet-piling.

Fortunately for the ordering, the Department of Docks and Ferries had complete data, as a wooden pile with a steel shoe had been driven at the corner of each cell or pocket, down to rock. From the rock elevation thus obtained, and assuming a plane surface between the corners, a schedule of piles was made up in lengths varying by 3 in. There were finally more than 3 500 piles in the order. If any one has a similar order to make up, it would be better to use 1 ft. as the variation in length, so as to have to deal with a less number of different lengths.

After giving the matter some thought, it was decided to record the pile data on loose leaves in book form, of a size that could be readily carried in the pocket. The pages contained the necessary information for the rolling mill, the contractor, and the Dock Department, and copies of the books were sent to all parties concerned. As each then had the same information, correspondence and conversation could be readily carried on.

The Lackawanna pile, in cross-section, is symmetrical as to the ends, but not the sides, therefore, the names of "right hand" and "left hand" were adopted, on account of the resemblance of the cross-section to the hand, when looked at from the thumb side. All specials were made by splitting the piles and using the halves, so that the end sections must present a certain outline to suit the closing of a pocket with a fixed number of piles—if an odd number, one outline, if an even number, a different outline—so this end section had to be shown also. The number of piles in the side of a pocket was finally decided on as an even number. This made the three wings of a Y-pile show right-handed in plan. The book solved this problem, as it gave the same information to all persons connected with the work, from the mill to the foreman who drove the piles, and the official who inspected them.

The next problem came in the handling. On the first few cars the piles were in no particular order, different cars even became mixed on the railroad lighter and in handling them from the railroad lighter to the contractor's lighter, or to the scows on the work, so that finding a pile of the required length was quite a task, and the loss of time increased the cost. The manner of handling the piles was discussed by the contractor's force and the railroad company, and the speaker went to Buffalo and arranged to have the piles loaded in the reverse order to that in which they were to be driven. The piles were stacked in groups of about eleven pieces each, with a maximum weight of about 11 tons per group. These groups were put on two cars, three

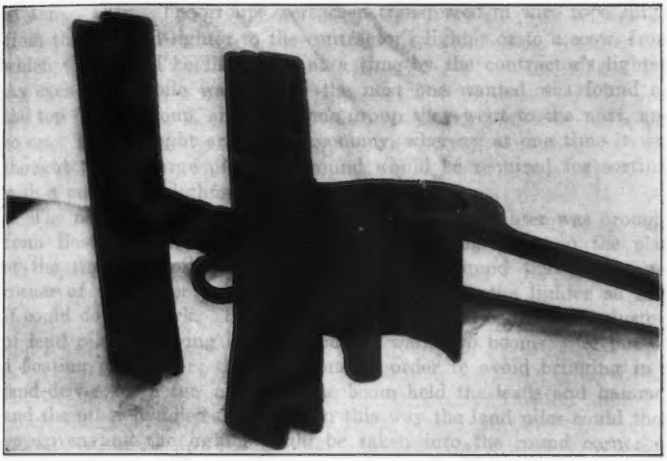

FIG. 37.—GUIDE FOR ENTERING PILE.

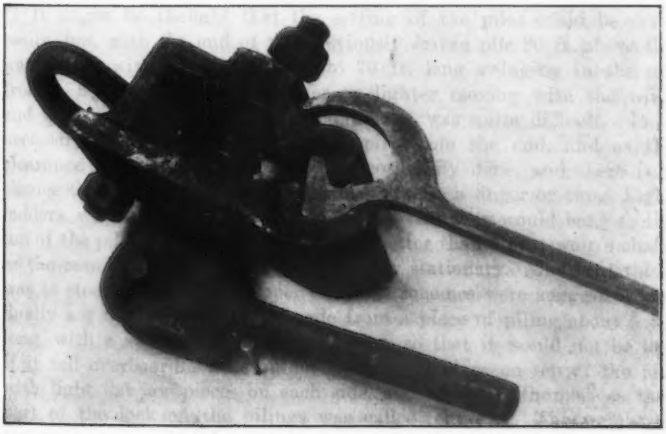

FIG. 38.—SPRING CLAMP FOR ATTACHING TAG LINE TO PILE.

Mr. Cudworth.

groups sideways and two groups high, separated both horizontally and vertically by blocking, so that the groups were unloaded as units in Jersey City. The groups were then transferred in wire rope slings from the railroad lighter to the contractor's lighter or to a scow, from which they could be lifted one at a time by the contractor's lighter. As each single pile was placed, the next one wanted was found on the top of the group, and from one group they went to the next, and so on. This brought order and economy, whereas, at one time it was thought that a large piece of ground would be required for sorting, with a crane or a lighter to do the work.

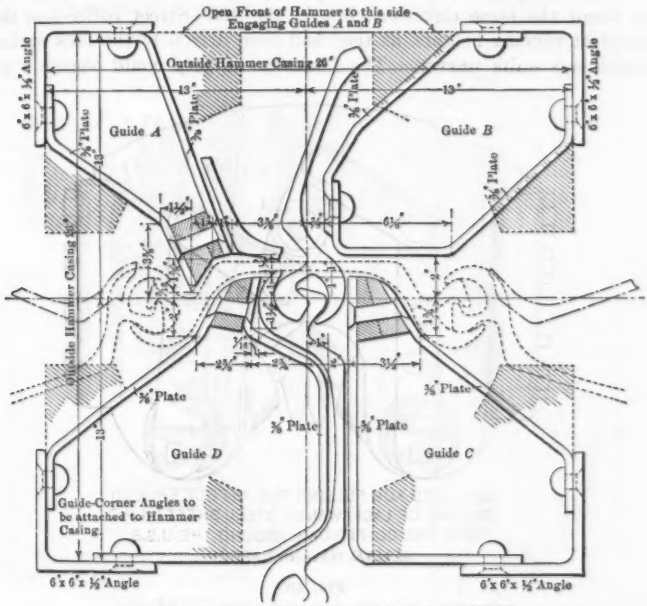
The next operation was setting the piling. A lighter was brought from Boston for this purpose, but, in sketching it in on the plan at the time the piling was ordered, it was found that the round corner of the coffer would not admit of placing the lighter so that it could do the work. To accomplish this, and also drive the clusters of land piles for tying back the cut-off wall, two booms were put on a floating pile-driver; this was done in order to avoid bringing in a land driver for a few clusters; one boom held the leads and hammer and the other handled the pile. In this way the land piles could then be driven and the lighter could be taken into the round corner of the dam "head on," in order to set the steel piles. The driver had little freeboard, but this was remedied by closing the forward hatch to keep the water from flooding the hold. This is the only case known to the speaker where two booms were used on a pile-driver. It was also intended to use these booms later for handling two driving hammers at the same time.

It might be thought that the setting of the piles could be done easily, but, with the end of the previously driven pile 20 ft. above the water, and with a pile from 50 to 70 ft. long swinging in the air from a boom, and the pile-driver or lighter moving with the wind and boat swells, it will be realized that it was quite difficult. It is necessary to enter the Lackawanna pile from the end, and as the clearance is only $\frac{3}{8}$ or $\frac{1}{2}$ in., this is not easily done, and there is a chance that the man guiding the pile may lose a finger or two. Light ladders, with a strong hook in the side, so that they would hang to the top of the pile, were provided, and were better than a boatswain's chair, as the man was on something more nearly stationary. The next thing was to steer the pile into place. Various schemes were suggested, and finally a guide (Fig. 37) was made from a piece of piling about 5 in. long, with a swivel-eye for a safety line, so that it would not be lost if it fell overboard. This guide was held in place on top of the pile with light flat-jaw pieces on each side, and had the "thumb," as that part of the lock on the pilings was called, cut out. The weight of the guide was reduced to 11 lb. by cutting. An operator, skilled in

Mr. Cudworth.

handling a lighter, could lower the pile within the distance of the height of this guide; it could then be pulled into place, and would be held by the "finger" of the guide until lowered. This was a time saver and good accident insurance.

The tag line at first was tied to the lower end of the pile, and two men on two lines held the swing of the pile, and helped the guide man. It took time to put on this rope, and more time when the pile was up in the air, to take it off. A little spring clamp (Fig. 38) was finally made, with a swivel-eye for attaching the tag-lines. The clamp was fastened to the pile with a screw bolt having a lever handle, and this could be put on and taken off in a few seconds. The weight of the clamp was 14 lb.



The best day's work in setting, with one lighter, after the crew had been well broken in, was in one case 98 pieces 70 ft. long, and in another case 129 pieces, from 20 to 25 ft. long, in 8 hours. In the latter instance the average was 16 piles per hour, or a pile in a little less than 4 min. Thus, seconds cut off in different ways were important.

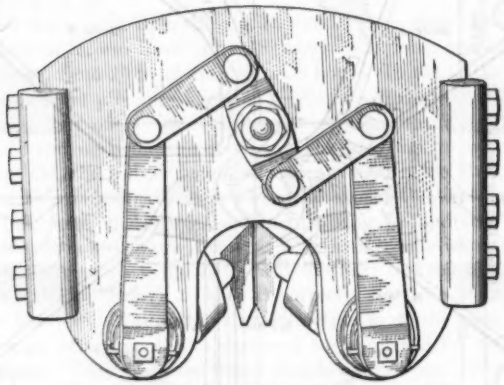
After the setting came the driving. The idea was to use the pile-driver boom and the lighter boom, and do away with the clumsy hanging leads. This is difficult, even when the suspension is from a land machine, but, with a floating machine, moving around and bobbing up and down, it is still more difficult. The first trouble was to get the hammer on the pile when up in the air, the next to keep it there, and lastly (but still important), to keep it correctly lined up with the pile, so that the blows would be in the right direction to do the most good.

Finally, an attachment was designed to be placed on the corners of the hammer. This projected like a double clothes-pin. The hammer was the body of the clothes-pin and the attachments were the prongs. This was built in iron and later in wood. Fig. 39 shows the design for the arch-web style of pile; the arrangement for the straight-web pile section was similar. A double set of prongs—making two slots—was used, so that, by placing the piles in one slot, either three or one could be driven, and by using the other slot, two piles could be covered. The idea was to drive three piles at a time when they drove easily, then two piles, when the driving was harder, and finish by driving one pile at a time, with a follower. This arrangement worked well, and allowed the lifting tackle to be even entirely slacked off, if desirable. In fact, the hammer would work on the pile without being otherwise supported. As shown by Fig. 42, this arrangement was also convenient for taking care of the hammer when not in use, as it saved laying it down on the deck of the lighter.

The problem of pulling the piles was a subject of much discussion, both in the field and in the office. On most of the jobs where piles have been pulled heretofore, with the exception of the coffer-dam

around the *Maine*, and part of the Black Dam, they had been driven in straight lines, or, if curved, the external was greater than the internal pressure, and they were not necessarily in tension in the locks. Owing to the manner in which the cells at 46th Street were filled, the internal was greater than the external pressure, so that the cells probably took a shape somewhat similar to a barrel, that is, they had swelled out in the middle from the pressure of the materials con- Mr. Cudworth.

HORIZONTAL CROSS-SECTION LOOKING DOWNWARD



ATTACHMENT TO HOLD HAMMER ON ONE, TWO, OR THREE PILES. (LACKAWANNA ARCH WEB SHAPE.)

FIG. 39.

tained in them, the bottom being held in place by the penetration. The piles to be pulled had been in place for about 2 years, and the earth friction was great. To this was added also the friction due to the tension locks and any additional friction resulting from the effect of the movement of the dam; thus it was difficult to determine the pull necessary to take them out. The locks, however, had been greased when driven.

Mr. Cudworth.

The problem was how to grip the pile and also be able to let go of it when desired, and how to arrange for the pulling. For taking hold of the pile, the Lackawanna Steel Company was kind enough to lend the contractors a 50-ton and a 150-ton grip, which would engage the web of the pile. (Fig. 40.) These grips were used in pulling the piles in the coffer-dam around the *Maine*, and were of the box form, which allowed the pile, as it was pulled, to come up through the inside of the grip. Where these grips had been used previously, the tops of the piles were at about the same elevation; but in the 46th Street coffer-dam they stood at varying heights, as they had been driven to the rock surface, which was quite uneven. The Lackawanna grip could engage a pile

GRIP USED FOR PULLING THE 75-FOOT SPLICED LENGTHS OF LACKAWANNA STEEL SHEET-PILING FROM THE COFFER-DAM AROUND THE U.S.S. *MAINE*, HAVANA HARBOR.

FIG. 40.

about 8 in. below the piles of either side, but when there was more than that variation it was impossible to apply the grip. To overcome this difficulty the speaker designed a grip of such width that it could go in the 8-in. space between two alternate piles and grab one which was lower. This grip (Fig. 41) had 4 by 16-in. side pieces, closed by a toggle and made to open by a single line operated by the engine runner. This was designed for a 60-ton pull. It was to be used in connection with the No. 1 National Pulling Hammer, as shown in Fig. 43.

This apparatus seemed to be strong enough to do the work. The first piles were pulled in the cut-off with a derrick of about 12 tons capacity. This combination pulled the piles which were shorter than about 25 ft., and then there was difficulty. In this case, due to the

Mr Cudworth.

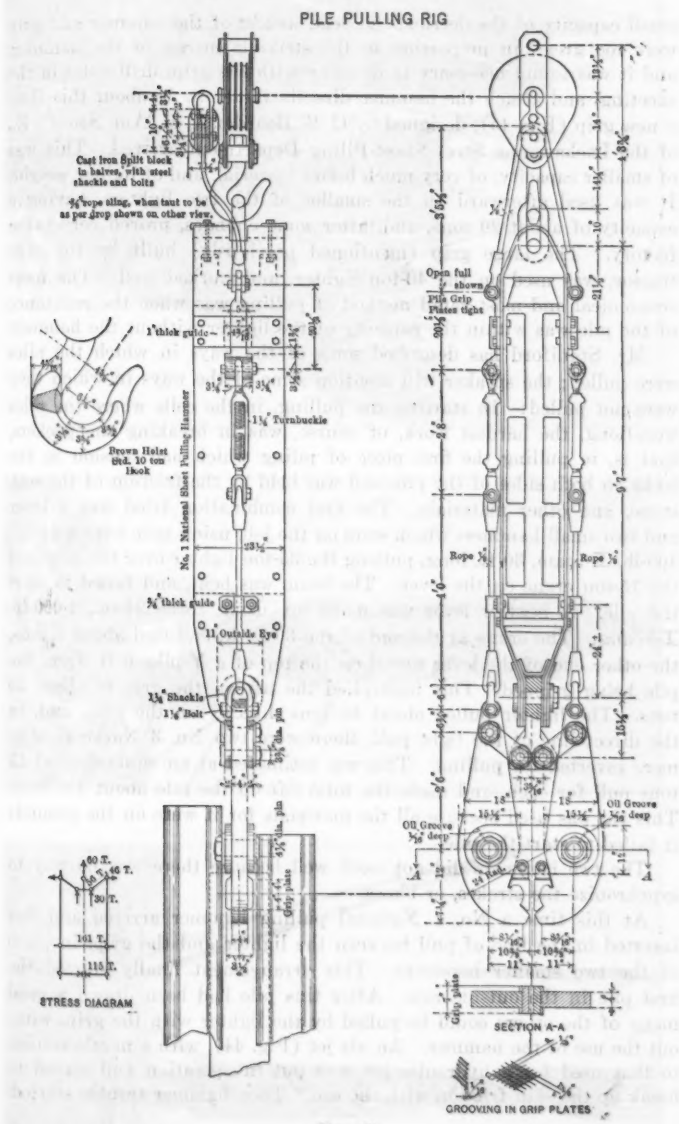


FIG. 41.

Mr. Cudworth.

small capacity of the derrick, the dead weight of the hammer and grip were too great, in proportion to the striking energy of the hammer, and it was found necessary to do away with the grip, drill holes in the sheeting, and attach the hammer directly thereto. At about this time a new grip (Fig. 45), designed by C. S. Boardman, M. Am. Soc. C. E., of the Lackawanna Steel Sheet-Piling Department arrived. This was of smaller capacity, of very much better material, and of lighter weight. It was used afterward on the smaller of the two lighters, having a capacity of about 20 tons, and, after some changes, proved very satisfactory. The large grip (mentioned previously) built by the contractor, was used on the 40-ton lighter, and worked well. The most economical and most rapid method of pulling was when the resistance of the pile was within the capacity of the lighter without the hammer.

Mr. Staniford has described some of the ways in which the piles were pulled; the speaker will mention some of the ways in which they were not pulled: In starting the pulling, in the cells where the piles were long, the hardest work, of course, was in breaking the pockets, that is, in pulling the first piece of piling which had tension in the locks on both sides of the pile and was held by the friction of the soil, stone, and other materials. The first combination tried was a lever and two small hammers which were on the job, using as a lever a 24-in., 100-lb. I-beam, 30 ft. long, putting the 35-ton lighter over the grip and the 15-ton crane on the lever. The beam was bent, and failed to start the pile. A heavier lever was made up, using three 24-in., 1 000-lb. I-beams. The crane at the end of the 30-ft. lever lifted about 8 tons, the other end of the lever rested on the top of a Y-pile, 6 ft. from the pile being gripped. This multiplied the lift on the grip to about 30 tons. The lighter pulled about 40 tons directly on the grip, and, in the direct line of the light pull, there were two No. 3 National hammers inverted for pulling. This was estimated at an equivalent of 15 tons pull for each, and made the total lift on the pile about 100 tons. This rig was used because all the materials for it were on the ground; it failed to start the pile.

The two hammers did not work well because there was no way to synchronize the strokes, or blows.

At this time a No. 1 National pulling hammer arrived and was inserted in the line of pull between the lighter and the grip, in place of the two smaller hammers. This arrangement finally started the first pile in the outside row. After this pile had been drawn a good many of the others could be pulled by the lighter with the grip, without the use of the hammer. An air jet (Fig. 44), with a nozzle similar to that used for a hydraulic jet, was put in operation and served to break up the skin friction with the soil. Then hammer trouble started.

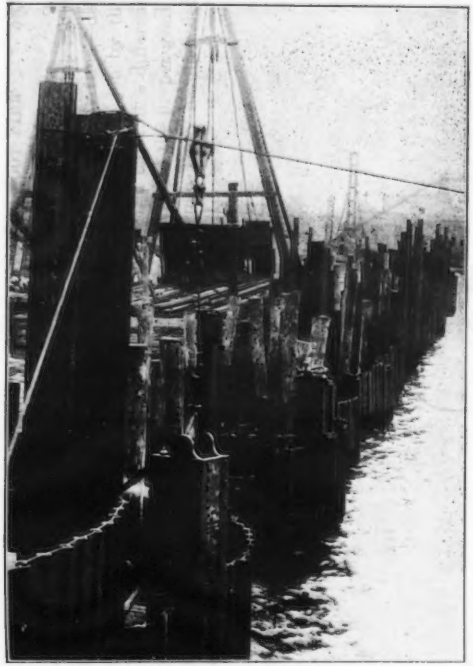

FIG. 42.—HAMMER IN OPERATION.

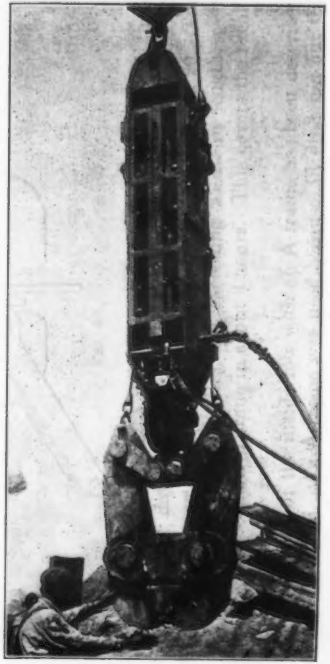

FIG. 43.—PULLING HAMMER AND CONTRACTORS' GRIP.

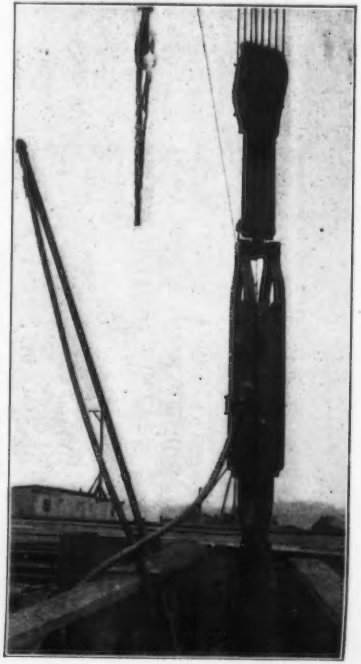

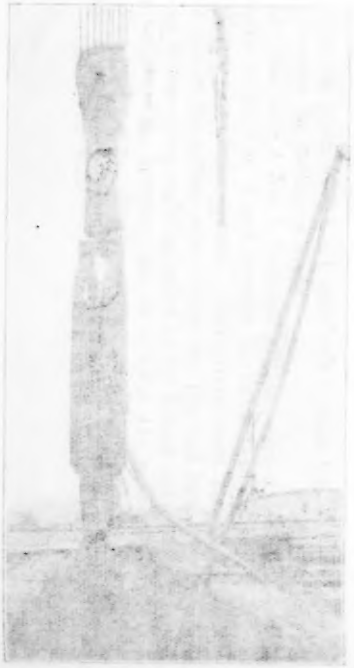

FIG. 44.—HAMMER INVERTED FOR PULLING.

Mr. Cudworth.

The band plate, which was of structural material—the best that could be obtained under the market conditions prevailing at that time—did not last very long, and a No. 6 hammer, brought to the job by the McKiernan-Terry Drill Company (Fig. 44), with a band of a different shape was used, as the other bands were expensive and the proper grade of material could not be obtained. The McKiernan-Terry hammer did excellent work.

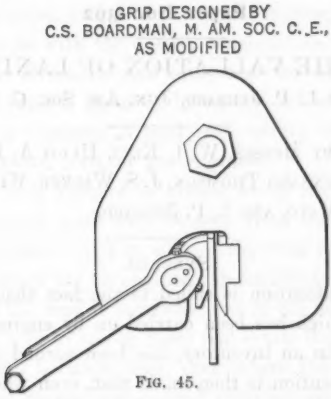

FIG. 45.

The pulling was a fight with the piles from start to finish, there being very few days when a good run could be made. The number pulled by one gang ranged from 0 to 40, a fair day's run was 20. The record was made when 66 piles, not exceeding 25 ft. in length, were pulled with a locomotive crane in about 6 hours. This covers the breaking of the outside row.

The breaking of the inside row with an **A**-frame has been described by Mr. Staniford. An **A**-frame was used because, in dredging out the pockets to a depth of about 10 ft., there was not enough of the dam remaining to carry the weight of the cranes.

Paper No. 1392

THE VALUATION OF LAND*

By L. P. Jerrard, Jun. Am. Soc. C. E.

With Discussion by Messrs. W. I. King, Hugh A. Kelly, Edward S. Rankin, T. Kennard Thomson, J. S. Walker, William J. Boucher, Franklin F. Mayo, and L. P. Jerrard.

Synopsis.

In this paper attention is called to the fact that, in the extensive valuation work which has been carried on by engineers in late years, the item of land, in an inventory, has been turned over to real estate dealers. The contention is then made that, even where the services of reliable and well-informed dealers are secured, their appraisals are not entirely satisfactory, and that it is well within the province of the engineer to check the values submitted to him, or even to make the determination of land values himself.

After some discussion of this point, there follows an exposition of the methods and procedure to be used in valuing land, a brief outline of which is as follows:

The principles of land values;
Sources of data regarding land values;
Method of utilizing the data;
Rules for long and short lots;
Corner lot rules;
Plottage;
The cost of acquiring land;
Values based on special utilization;
The valuation of railroad land;
The cost of land appraisals.

* Presented at the meeting of December 20th, 1916.

In recent years there has been a great increase in the demand for valuation of physical property of every description. One great stimulus has perhaps been the organization of public bodies for the purpose of investigating and regulating semi-public corporations, but modern methods of accounting and keeping records are also an important factor. The work of making these valuations has naturally fallen into the hands of engineers, owing to the fact that they, more than any one else, have had to do with the design, construction, and in many cases the selling, of the structures and equipment for which an appraisal is demanded. The various items of inventory—of which, with some exceptions, the most common is land—fall within the knowledge of an electrical, mechanical, civil, or gas engineer.

The item of land appears in almost every inventory, and its importance in appraisal work may be seen from the fact that its value ordinarily constitutes from 5 to 50% of the total value of a utility. It is probably customary for an engineer, in handling a valuation proposition, to feel that the land is somewhat out of his field, and to turn this part of the work over to one or more real estate dealers. In this paper the contention will be made that, even where the services of reliable and well-informed dealers are secured, their appraisals are not entirely satisfactory, and that it is well within the province of an engineer to check the values submitted to him, or even to make the determination of value himself. In some of the greater cities large real estate offices maintain highly organized appraisal departments and, unquestionably, no one is better qualified to make land valuations in certain territory than they are, but it is held that in the country at large the average real estate dealers' appraisals are likely to be in error, due to carelessness, prejudice, or incompetence. It is proposed to show that land values are fixed by more or less definite forces, and to indicate how, by the systematic collection and application of data, a man unfamiliar with land values, as a dealer or even as a near-by resident, may obtain reliable appraisals.

The development of the methods suggested herein should be useful, not only in valuation work, but also in acquiring land for utilities, and especially in cases where controversies arise. In a contest, a real estate broker testifies that he has been a land dealer for a certain number of years, that he has platted and sold land in the vicinity of the tract in question, and that in his opinion the tract is worth a certain sum. In

some cases the very sales he himself has made would, if analyzed, disprove his contention. In what a multitude of cases have not city and county authorities, railroad companies, and other corporations been forced to pay exorbitant sums for land on evidence of this character! In no case may an appraiser gather data enough actually to prove the value of a tract of land, and in the end his conclusions represent his opinion only, but he can present logical reasons for his opinion, and can generally submit enough facts to define a value within narrow limits.

In approaching this subject, it should be borne in mind that land has a value as a result of the operation of definite economic, political, or social forces, and that changes of value take place by reason of similar forces. The location of cities does not occur at random, nor does their growth take place by chance; likewise, the development of farming communities is regulated by their natural facilities. It is the consideration, then, of the factors which affect land values to which the writer will proceed.

The true value of land is the ground rent capitalized. The ground rent is the net income which remains after paying the taxes on the land and the taxes, depreciation, interest, and maintenance on all improvements. The market value may be entirely different from the true value, as it is based, not only on the ground rent capitalized, but on the future prospects of the land's utilization. Farm land differs from city land in that the fertility of the soil, in addition to the advantage of location, is a source of ground rent. Farm land values are comparatively simple, however, and will be treated briefly before taking up city land values, as the latter are much more important.

The value of farm lands depends primarily on the fertility of the soil. Other factors are the topography, water supply, climatic conditions, and the development of the community as regards markets, highways, schools, villages, etc. The advantages of location consist in nearness to cities, railway stations, and schools. The value of farm land is comparatively low and the range of values small. The factors just mentioned vary but little over large areas, and consequently the change in values is gradual. The problem of determining farm land values, therefore, is comparatively simple, because any data which may be obtained are generally applicable over a large district.

The Structural Development of Cities.

The problem presented by cities is much more complex. In the first settlement of new territory, land has no value. A settler has his choice of numerous locations, and occupies any tract that suits his fancy. As other settlers appear, however, there comes a time when there is a difference in desirability between two tracts, due to their location. It is at this point that value arises in the land having a superior location, and it becomes a source of ground rent. As the community grows, more distant lands come into use, a larger area of land has a value, and the value of the best location is forced higher. When the proportions of a city are reached, the grades of land are very numerous, and they are occupied by a variety of utilities. City land is useful only as a site for buildings, and advantages of location govern the values entirely. Any location in the city may be sought by any utility, and the land goes to the one which can make it yield the highest ground rent and, therefore, pay the greatest price for it.

City land may be divided roughly into the following classes as regards utilization:

Distribution.—Retail stores, wholesale stores, railroads.
Administration.—Banks, office buildings, public buildings.
Production.—Factories.
Residence.—Dwellings, tenements, apartments, hotels.

There are other utilizations, such as theaters, hospitals, libraries, etc., which do not fall readily under these classes, but they do not form a large percentage of the total number of utilities. For each of the utilities in this classification there is, with respect to other utilities, a portion of a city within which it is almost forced to locate.

In retailing, the seller must draw the buyer into his establishment. He seeks a location where the largest number of prospective customers will pass, and, consequently, retail stores gather at the heart of the city. Wholesale dealers locate where transportation facilities are best, and as close as rentals will warrant to any retailers whose business they may seek to hold or obtain. Railroads procure sites close to the business center in order to secure passenger traffic, and their freight terminals are located in the wholesale and manufacturing districts. Banks and office buildings are found in the business center, but they can scarcely compete with retail stores for the best locations. Manu-

facturing, to some extent, has the same requirements as wholesaling, but, in addition to railroad facilities, their labor conditions must be considered.

The basis of business values is strictly economic, the land going to the highest bidder, but the basis of residence values has a social element. The wealthy class select the best locations, near parks, easy of access, and free from nuisances. Those of lesser means take locations as near them as possible, and the poorest people are obliged to live in the outskirts of the city or in undesirable places near tanneries, railroad yards, gas plants, etc. Apartment houses are distributed about the same as dwellings; and hotels locate near the retail stores, theaters, and passenger terminals.

The conspicuous feature in cities is the tendency of utilities in the same business to cluster together. The influences which favor one are favorable to another, and, moreover, each establishment endeavors to benefit by the business which other concerns draw. A buyer in a city may visit a number of wholesale houses by traversing a small district, and a jobber located in some other part of the city would probably not receive his attention. In every large city, then, there will be found at the center a business section, certain portions of which are occupied by different groups of utilities, such as retail stores, banks and financial institutions, jobbing houses, etc. Surrounding the business center are sections occupied by the several classes of residence structures, by storage warehouses, factories, railroad yards, and many other utilities. The lines of demarcation between these sections are generally not well defined, as the change from one class of utilization to another is for the most part gradual. It is not uncommon, however, to find two distinct classes of utilization separated by a single street; and barriers, such as a river or a railroad line, often constitute sharp division lines.

The increase in population, the changes in style of architecture and types of construction, and the constant depreciation of buildings cause a continuous movement of utilities from one district to another. In a fine residence section the houses eventually become old and out-of-date, and, as a result, more modern dwellings are built in new districts elsewhere in the city. The old section soon begins to lose its reputation as a fashionable district, the wealthy people gradually move out, the vacated dwellings are used for boarding houses, and the section suffers a decline in land values, even as a rise in values is experienced in the

new district. It is possible for real estate men to gain control of a district, and, by platting it in a suitable manner, making street and park improvements and placing building restrictions on all lots sold, to develop a good residence section. Similarly, by filling in low lands or providing railroad or harbor facilities, a manufacturing or shipping district may be fostered. Frequently the movement of groups of utilities, and consequent changes of land value, are regulated by activities along such lines. In many cases the movement of utilities from one district to another is guided more by the natural growth of the city and the development of its transportation systems, and cannot be influenced as in the foregoing instances. Business property is the least susceptible to such influences.

Business remains on level ground and where topography does not interfere, the retail section moves in the direction of the best residence section. The reason for this is that the residents of such a section represent the heaviest buyers, and their custom is sought by all shops, not alone for the value of their patronage, but also by reason of the fact that all classes go to the shops where the wealthy class trades. The advance of a retail section toward a residence section involves the movement of banks and offices into new districts. The buildings vacated by shops, offices, and banks must necessarily succeed to a lower utility, such as wholesale houses and factories, and these are often followed by tenements and vacancies, so that land once the best in the city sometimes drops to a low value. The point of highest value is constantly moving, and, unless the increase in population is sufficient to overcome the tendency, the land behind this movement suffers a decrease in value.

City Land Values.

From the business center, the main traveled streets project axes of higher value into the outlying territory. As a rule, values grade down regularly from the point of highest value at the business center to the outskirts of the city, and also grade down on each side of the main traveled axes radiating from the heart of the city. This general scheme of values is modified by the location of railroads, bridges, parks, and the different classes of utilities, and also by the topography, kind of platting, extent of street improvements, etc. It is not common to find sharp differences in the values of two adjoining properties. Where a district of low utility adjoins one where land values are compara-

tively high, the low-class land near the boundary is of greater value than the remainder of the district, owing to the proximity of higher values, and, correspondingly, the high-class land near the boundary reflects to a certain extent the low values near-by. Marked changes of value take place, not by sudden variation, but by degrees, over a distance of several blocks.

The total land value of a city depends primarily on the population, but is influenced to so great an extent by the city's wealth and other factors that comparisons between cities of the same population, as to either the total land value or the value of highest priced land, offer considerable variation. It is believed that the range of values in Fig. 2 will cover the conditions in all except a very small percentage of cities. The lower values represent more nearly the normal conditions, and the higher values occur in cities where there is a large transient population or where the business district is restricted. All factors which tend toward the expenditure, in a city, of money which is earned elsewhere, raise the value of business land. For instance, the location, in a city of 25 000 people, of a university with several thousand students would materially increase business land values above those of other cities of the same size. In determining the population of a city, there should be considered such suburbs as are close enough to constitute a part of the city proper. The 1910 census shows the population of Boston to be about 670 000, but the addition of Cambridge, Somerville, Winthrop, and other communities which directly adjoin the city and are closer to the business center than some parts of Boston proper, brings this figure up to nearly 1 000 000. Entering Fig. 2 with this latter figure, the value of the best business land is seen to range from $9 000 to $15 000 per front foot and, when the great tributary and transient population of the city is considered, one would expect to find there, as is in fact the case, values corresponding to the higher figure.

It will be seen from the foregoing that an investigation of land values generally involves a study of the forces at work in a city's development, the land requirements and distribution of its utilities, and the strength and direction of the structural movements which are constantly taking place. The extent of such a study would depend, of course, on the land under consideration. In valuing a single lot in a residence section, such preparation would not be called for, but, in the case of high-priced business land, it is necessary to be informed on these points.

FIG. 1.—MICHIGAN AVENUE, CHICAGO, FROM PARK ROW, IN 1864. THE BUSINESS CENTER OF A CITY MOVES TOWARD THE BEST RESIDENCE SECTION.

For the purposes of this paper the "market value" of land will be considered as the ordinary exchange price that one party would pay another for a farm, city lot, or other tract of land, under normal conditions, that is, when the purchaser is not compelled by circumstances to pay an excessive price nor the grantor to sell at a sacrifice. The market value will not include additional amounts which are often paid for plottage, severance charges, or damages; also, the term "front foot" will be made to mean a strip of land having a frontage of 1 ft. on a street and a depth of 100 ft. measured at right angles thereto. The unit used in measuring city land varies in different parts of the country. In some places it is the custom to use the front foot of 100-ft. depth, or some other depth, and in other places the square foot is the unit. Those accustomed to think of land values by the square foot can readily convert the figures in mind to the front foot as used herein by multiplying by 100.

Sources of Data for Determining Land Values.

In making land appraisals, the following classes of information are available:

Inspection and general study.
Sales of real estate.
Tax assessments.
Rentals.
Opinions of land dealers.
Opinions of land owners.
Character of buildings, as an index to land values.
Real estate for sale.

Inspection and General Study.—In connection with any property, there should be obtained at the outset all information with regard to the dimensions of the tract, the accuracy of the survey, the condition of the title, the amount of taxes and special assessments due, and the existence of mortgages or restrictions as to the use of the land. An inspection is generally necessary in order to determine the extent and condition of street improvements, and the nature of the property as regards topography, filling, protection of water frontage, etc. A general study also involves some investigation of the district in which the property is located and of the city's development and structural growth, as heretofore outlined. A knowledge of general conditions enables an

appraiser to make use of data which are not directly applicable to the land in question, and often establishes limiting values on a tract of land before a detailed study is undertaken. It is always advisable to be provided with a map showing, not only the parcel of land in question, but the surrounding district for a good many blocks on every side. By recording on this map sales, assessments, rentals, topographic features, etc., their bearing on land values may be most clearly understood.

Sales of Real Estate.—Actual sales of real estate offer one of the best criteria of land value available to an appraiser. Where they can be found in sufficient numbers to form a basis for the judgment, there is no better evidence of market value. In residence districts, where transfers are always taking place, and in the newer portions of a city, where sales are numerous, the work of an appraiser is simplified. After a list of sales has been obtained for land valuation purposes, the appraiser should go to the public record and read the deeds, in order to cull out transfers which do not show true values. Some of the reasons for which sales should be rejected are nominal consideration, material reservations or restrictions, only part interest conveyed, personal property included, conveyance to perfect title, trade, deal between relatives, conveyance to railroad company or municipality, scattered parcels in one conveyance, sheriff's deed, tax deed, etc. These facts cannot always be determined simply by reading the deed, and there are other reasons for rejecting a sale which are almost sure to escape observation by that method. Among such are conveyances by swindlers, fictitious considerations, company and partnership deals, and land contracts. It is advisable, therefore, in important cases, to learn as much as possible regarding the circumstances under which a transfer of real estate is made.

The use of sales is subject to the following disadvantages:

1.—Large numbers of sales are recorded with a nominal or fictitious consideration, and it is often difficult to learn the *bona-fide* sale price. This is more particularly true of high-priced land.

2.—As land reaches high values, the proportional number of sales decreases, so that in certain classes of property such as high-class business land, or dock property where harbor space is limited, the sales data are very meager.

3.—Sales of real estate often include buildings which must be separated in order to determine the sale value of the land alone. In cheap properties many vacant lots are sold, but where land reaches a high value it is not allowed to stand idle, and a sale price is sure to include more or less extensive improvements. In a considerable portion of the high-priced property that comes to sale, the improvements are old, poorly designed, or not suited to the location. These propositions generally involve the wrecking or remodeling of a building, and the apportionment of the sale price between value of improvements and value of land is a doubtful process.

It may be seen, therefore, that sales are more directly useful in appraising cheaper lands, such as ordinary residence sections, where values are low and changes of value gradual, but that their availability decreases in somewhat the same proportion as land increases in value.

Tax Assessments.—Assessments of real estate for taxation purposes are generally considered to be of little or no use as a guide to land values, and it is true that the average city assessment exhibits many irregularities. The assessments are made, however, by men whose particular business it is to study the values in a certain section, and as most of them gain great familiarity with their districts, the figures determined by them are a valuable aid to the judgment. Assessments may be faulty in two particulars: first, in that the different parcels are not assessed on the same basis; and, second, in that the whole district is not assessed at full market value, but at some percentage thereof. The best way to determine whether an assessment is well equalized is to reduce the figures in the section to the same unit, such as dollars per front foot, per acre, or per lot, and plat them on a map. Irregularities show up very clearly on such a graphical representation. As a rule, however, an assessment will be found to be fairly good as regards the comparative value of different parcels, especially where it has been developed during a period of years. Taxpayers are constantly comparing their assessments with those of their neighbors, and, as marked differences meet with complaint until rectified, the tendency is always toward better equalization. It should be noted that not all assessments separate land and buildings, for in many communities the sum of the two appears as one item on the public records. In such cases the assessment

on land alone cannot be obtained, unless, as is often the case, it is obtained from the private records of the assessor.

It is possible, then, where land assessments are available, for an appraiser to make an examination of them and, by the elimination of irregularities and discriminations, determine a fair assessed value for a given piece of land. It only remains, then, to determine what percentage the assessment bears to the true market value. This is done by gathering *bona-fide* sales of property, ascertaining the assessed value of such properties, and computing the ratio of assessed value to market value. For this purpose it is possible to use sales throughout a small area surrounding the tract in question, or a ward, or even an entire city. This method amplifies the use of sales data very materially, for it permits the use of sales which have no direct bearing on the land being appraised, and, moreover, is not affected to such a large extent by the fact that real estate sales involve the value of improvements. Assessments, therefore, when carefully studied and used in connection with land sales, constitute valuable evidence with regard to land values.

Rentals.—If ground rent is determined it is possible to capitalize it and arrive at a value for the land. This process involves gathering considerable data and the use of very good judgment in choosing a rate of capitalization. Ground rent is computed by deducting from the gross rental the taxes on the land, and the taxes, insurance, interest, maintenance, and annual depreciation on the improvements. There are modifications of this procedure by which the gross rental, or the gross rental less certain items, is capitalized, and the rate of capitalization is increased to allow for the items just mentioned which are not deducted. There is a disadvantage in using gross rentals, however, for when capitalized they represent the land and buildings together, and there remains the difficulty of separating the value of land from that of the total improved property. On the other hand, the amount of ground rent as computed may fluctuate greatly, due to the influence of management, and it is necessary to know that a property is well administered, lest the ground rent as determined be too low or even nonexistent. It is also necessary to use current rentals, for rentals agreed upon at some previous time may reflect incorrect values, and this is especially true where land values are changing.

The rate of capitalization follows the same course as the yield on securities, and depends on the safety and permanence of the earning

power. The rate ranges from 4% for the best property in large cities up to 8 and 10% for poor properties in small cities, and even higher for land suitable only for temporary or disreputable utilization. The rate varies in different cities, and, as a rule, is lower in the Eastern States than in the West or South. In a district where land values are increasing, the rate of capitalization is below normal, and where values are decreasing, it runs very high. As previously stated, the use of rentals requires care and good judgment in order to obtain satisfactory results.

Opinions of Land Dealers.—The most common method of ascertaining the value of land is to consult real estate dealers, but, in a large number of cases, their figures are found to be unsatisfactory. The average real estate dealer's appraisal represents an inspection, some thought on such sales and rentals as he is familiar with, and an interview possibly with some other dealer, but no systematic collection and presentation of data. Sometimes great carelessness is displayed in their work. As an instance may be cited the case where several dealers made valuations of a piece of dock property, ranging from $75 to $200 per front foot. Some of them evidently overlooked the fact that the property was not accessible from any street except by passing a long distance over land belonging to another owner, for, in consideration of this fact, the tract was transferred for $66 per front foot. As a rule, the successful real estate dealers' principal assets are nerve and salesmanship. They do not want honestly to know values, but to make sales. They possess an advantage, however, in their knowledge of sale and rental figures, and it is often necessary to gain their co-operation in order to obtain this information. Real estate dealers are generally optimists, and in their opinions often incline to high values, especially in the districts where they are selling lands. Ordinary prejudice, however, does not account for the almost incredible variation which is sometimes found in the opinions of real estate men regarding the same piece of land, which indicates that this class of information may be far from correct, and should be weighed carefully before being accepted as evidence on which to base judgment.

Opinions of Land Owners.—A land owner nearly always has a definite opinion as to the value of his holdings, even though he is not in the market for land, either as a buyer or a seller. This is held to be important information by some authorities on the ground that it is the opinion of land owners which fixes the market value of land. The

probabilities, however, are that the converse is much more often the case, and the opinion of the land holder is fixed by such knowledge as he obtains regarding sales. It is believed that in a great number of cases a land holder is not well enough informed to pass reliable opinions on land values, and that when he is competent it is difficult to obtain from him an honest expression. This class of information can be obtained readily, and should be given some consideration.

Character of Buildings as an Index to Land Values.—The cost of buildings is in a measure an index to the value of the lands which they occupy. In a large proportion of the buildings constructed for business purposes, the cost is about equal to the value of the land. There is, of course, great deviation from this rule, but marked departure is almost always accompanied by financial loss. A cheap building on expensive land is unable to earn an income proportionate to the high land value; and an expensive building on cheap land must necessarily be located outside the district where structures of its class are in demand. On this basis Table 1 has been prepared, showing the value of land occupied by the ordinary types of business buildings, in dollars per front foot, but it should be useful only for very rough estimating. There are numerous instances where there is a great variation in the value of buildings along a street on which lots have approximately the same value, and in such cases the tendency is for the land values to correspond more nearly to those of the highest structures. Exceptions to the general rule are frequent, as, for instance, where cheap structures are erected on good land to serve but a short time, while waiting a better opportunity to make permanent improvements on the property.

TABLE 1.

Size of building.	Construction.	Average value of land per front foot.
2-story	Brick and frame.	$150 to $200
3 "	" " "	250 to 350
4 "	" " "	400 to 500
5 "	" " "	600 to 800
6 "	Slow-burning.	1 000 to 1 500
8 "	" "	2 000 to 3 000
10 "	Tending to fire-proof.	3 500 to 5 500
12 "	Fire-proof.	5 500

Real Estate for Sale.—Although there may be no sales of real estate in a district, it is generally possible to find property which is on the market, and obtain an offer of sale. Such an offer throws light on land

values, but should generally be considered as establishing a maximum figure. A party in making an offer usually endeavors to get a high price at first and is obliged to lower his figure before a transaction is finally made. Such offers, consequently, represent values in excess of the market value. They constitute valuable information, however, and have the additional merit of being readily obtainable in the majority of cases.

Determination of Value.

Information bearing on land values may often be found by investigating the expert testimony given in damage cases and other Court actions or hearings, Probate Court records, inheritance tax appraisals, mortgage records, and tax disputes. In valuing land, there may be utilized one or more of the classes of information which have just been discussed. In a district where good sales are plentiful, a brief study of the transfers may be sufficient. As lands reach high values, however, the information bearing on them, not only exists in smaller quantities, but is more difficult to obtain, and often there are few enough data on which to base judgment, even after a careful investigation. The final determination of a market value is ultimately a matter of the judgment of the appraiser, and it is for him to decide in each case what information is required, and just what weight should be given to all the evidence finally obtained.

In summing up it may be said that the important steps in determining the market value of land are as follows:

1.—A thorough investigation of all conditions affecting the land in question, in order that no important considerations may be overlooked, as, for instance, the lack of street connections, in the case already cited.

2.—A systematic and thorough collection of information.

3.—A graphical representation of the data gathered, for by no other means may the relation which values bear to each other be so readily understood.

4.—Determination of value after weighing all evidence.

It should be remembered that the market value of a given piece of land is not a definite sum, and cannot be estimated with absolute accuracy. Several unprejudiced men, all working with the same data, will not obtain similar results. In certain cases it may be possible to

establish a definite market value on cheap vacant lots, but, when property values run into several thousand dollars, reliable estimates will vary 5%, and in complex situations 10%, 25%, or even more.

Long and Short Lots.—Having determined a market value of land, the next problem is the application of that value to lots of irregular size and shape, corner lots, and groups of lots. A market value of dollars per front foot refers to property of average depth, depending on the manner in which the city is platted, and it is frequently necessary to apply this value to a lot either shorter or longer than the average. Several tables have been compiled by different authorities showing the percentage of the total value of lots 100 ft. in depth which is represented by a lot of any other depth, either greater or smaller. A number of well-known rules have been tabulated and are submitted herewith in comparative form. The Hoffman rule appeared prior to 1870, and was based on the assumption that the front half of a 100-ft. lot was worth two-thirds of the total value of the lot. The 4-3-2-1 rule, which is as old, assumed that the front 25 ft. of a 100-ft. lot represented 40% of the total value, the second 25 ft., 30% of the value, the third 25 ft., 20%, and the rear 25 ft., 10 per cent. The Hoffman-Neill rule is a modification of the Hoffman rule, and the Newark rule was developed by the assessing body in the City of Newark. The Somers rule is the work of Mr. Somers, who was long associated with assessment work in New York City. Mr. Pleydell's rule is based on extensive studies in New York City; and the Lindsay-Bernard rule was developed from a mass of data gathered in Baltimore. The Milwaukee rule has been developed during a period of years by Mr. J. H. Leenhouts, connected with the Milwaukee assessing body, adjustments having been made from time to time as additional data warranted. In Milwaukee and Newark separate rules are used for business and residence property. The Davies rule is the work of Mr. William E. Davies, of New York City, and was adopted by him after a study of more than 10 000 sales. Most of the rules are based on a 100-ft. depth of lot, but the Lindsay-Bernard and Pleydell percentages are based on a 150-ft. lot. By a simple computation it is possible to reduce these percentages to the 100-ft. lot basis, as, for example, to find what ratio a 50-ft. lot bears to a 100-ft. lot, according to the Lindsay-Bernard rule, enter their table and divide the percentage for a 50-ft. lot by the percentage for a 100-ft. lot. This operation gives $58 \div 88 = 66$ per cent. This

computation has been made for all values in the rules which are not based on a 100-ft. lot, and recorded in Table 2 for purposes of comparison. Columns (1) to (11) have been platted on Fig. 3. All the rules are not shown here in their complete form, as some of them give a percentage for every foot of variation in depth instead of every 5 ft., and, also, some of them have the percentages worked out to three decimal places instead of two. Percentages for depths of lots other than those shown in the tables may be determined by interpolation, and the application of percentages worked out to one-tenth of 1% is a needless refinement, as market values cannot be determined with any such degree of accuracy.

FIG. 3.

Of these rules, the Lindsay-Bernard, Milwaukee, Davies, Newark, Pleydell, and Somers are based on actual investigations, and not on assumptions. Of these, the first three appear to represent the most careful study. The Milwaukee authorities have made an excellent point in distinguishing between residence and business property. It is entirely logical that such a difference should exist, and it is easy to understand that in business property a larger proportion of the value would lie in the front portion of the lot, as indicated by the curves. It should be noted that a curve drawn midway between the Milwaukee business and residence curves, and therefore representing average conditions, would coincide more closely with the results of other investigators. The Davies rule is probably more representative of conditions in the large Eastern cities, as it is based largely on data obtained in New York City. It is practically impossible for every appraiser to collect data and formulate his own rule, and it is necessary for him to use the work of others, choosing that which in his judgment appears most reasonable and is supported by the most thorough investigation. It should be noted here that not in every case does a short lot have a greater value per square foot than a lot of standard length. In a tenement district, for instance, a lot too short to be used for tenement purposes would have a lesser value per square foot than a lot of standard length. Such cases are infrequent, however, as such lots are eventually combined with other property, in order that their highest utilization may be attained.

The use of a rule for long and short lots enables one to place a value on a few square feet in any part of a lot, having given the distance to the street. For example, to find the value of a lot 20 ft. deep and 60 ft. from the street, just subtract the value of a 60-ft. lot from that of an 80-ft. lot, as determined from the rule. The application of this procedure to L-shaped lots and lots which have no frontage may be readily seen. Where the sides of a lot are of different lengths they may be averaged, that is, if one side of a lot is 60 ft. long and the other side 80 ft. long, obtain the value of a 70-ft. rectangular lot according to the rule used. Where lots are irregular in shape they may be divided into small squares, and the values of the squares may be determined and summed.

Value of Corner Lots.—A more difficult problem than long and short lots is presented in the determination of corner lot values. Vari-

ous formulas have been devised for computing the value of corner lots, having given the value per front foot of an inside lot on both the main and side streets. It would seem that any formula or rule for determining the corner influence would be inadequate, because the corner lot value is affected by a number of factors, among which are the value of land, the relation of land values on the main street to those on the side street, the width and depth of lots, the height of buildings, the kind of occupancy, and other conditions. In making a city assessment, it is almost necessary to use a rule, on account of the great amount of work to be done; and most of the authorities mentioned have devised a procedure for this purpose. It is felt that none of the rules is adequate, although some of them may be applicable in a majority of cases.

Mr. A. C. Pleydell's rule is to consider the corner as an inside lot on the main street, add 15% and also add 50% of its value as an inside lot on the side street and extended according to the Newark rule. This method is the result of careful study by Mr. Pleydell, but it is understood that he is not prepared to justify it entirely, and offers it more in the nature of a suggestion. A method of determining corner lot values has been worked out by Mr. W. A. Somers, of the Manufacturers Appraisal Company, of Cleveland, the basis of which is not made public. He states that the corner influence in all property generally extends 100 ft. each way from the corner, and he has compiled tables which indicate for any combination of unit values on the main and side streets the value of each 10-ft. square. The values of these squares may be summed to obtain the value of a lot of any shape or size within the 100-ft. corner square. It would seem that any rule applied with such mathematical precision is altogether too inflexible to meet the great variety of conditions which obtain with respect to corner lots.

The City of Milwaukee uses a rule which has been developed by Mr. J. H. Leenhouts, Chief Clerk for 18 years in the city Tax Commissioner's Office, with the co-operation of the Milwaukee Real Estate Board. It is stated as follows: For residence property where all street improvements are made, add 25% of the value of the main street frontage on a width of 30 ft. for corner influence. For business property add the value per front foot (computed as an inside lot and extended according to the Milwaukee rule for business property) of the main and

side streets, divide by two, and take 60% of the result, which determines the value per front foot to be added for corner influence on a width of 40 ft. on the main street. In all cases this method is subject to local conditions and the judgment of the appraiser. As regards business lots, the application of this formula nearly always adds less than 50% to the value of a corner property, as compared with an inside lot, and it is considered that the tendency is to give results which are too low. The Lindsay-Bernard corner lot rule consists in fixing the value of the property as an inside lot on both the main and side streets and adding the two. The sum is taken as the minimum value of the corner, and to it are added all minor factors of value which suggest themselves to an intelligent appraiser. This rule has been tested by its authors in the case of more than 400 sales and rentals, with good results. Although it yields much higher values than the other rules, it is considered to be the most satisfactory of them all.

Many real estate men simply add to a corner lot 50% of the value of an inside lot. Mr. E. H. Gilbert advocates the following procedure for New York City, where nearly all lots have a frontage of 25 ft. To the lot adjoining a corner lot add 10% of the value of an inside lot. To the corner lot add 60% of the value of the lot adjoining the corner. It is probable that a more reliable procedure is represented by a set of rules used by Mr. George C. Olcott, a real estate appraiser of Chicago. In some respects his method is not as definitely outlined as in some of the other rules mentioned, and consequently his system is more flexible.

Mr. Olcott's system of corner valuation is as follows:

"The value per front foot for inside lots of an average depth in any block having been ascertained, the value of the corner lot per front foot may be arrived at with approximate accuracy by the adoption of the following rules:

"On Residence Streets.—To the value per foot on the frontage street, add one-quarter of the value per foot of the side street.

"Thus, if the value of the street on which a lot faces has been placed at $100 per front foot for that block, and the value of the lots on the side street at $80 per front foot, the value of the corner may be safely called $120 per front foot.

"In estimating the value of corner lots on any street, 50 ft. is regarded as coming under the corner influence. If the 50 ft. is divided up into two holdings, the corner value with few exceptions applies only to the immediate corner lot.

"On Residence Streets in Transition to Business Streets.—To the value per foot on the frontage street add one-half of the value per foot of the side street.

"On Business Streets Outside Down-town Center.—To the value per foot on the frontage street add the full value per foot of the side street. The increase, however, should not be less than 25% of the high value unit.

"If a transfer corner, where the intersecting car lines run at right angles for some distance and do not parallel each other partly or wholly, a fair basis to start on is the full value per foot of the values placed on the four converging blocks added together. To this add such a percentage as may be suggested by length of distance traveled and population of tributary territory thereto of said lines. Local conditions, such as license district limits, population immediately around said corner, nearness of factory, church, or school, affect corner values favorably or otherwise.

"Perhaps as accurate results as by any method may be arrived at by estimating the value of all the corners on a given business street, in order to find the relative value of the particular one desired. Select the best corner on the street, then the next, and the next, to the least valuable corner. Get all the data possible, of sales and asking prices. Start from the ascertained facts and increase or decrease proportionately the value of the corners as they have been selected as better or less desirable than the ones from which the data have given a starting point.

"In Factory Districts.—To the value per square foot on the main frontage street, add three-eighths of the value per square foot placed upon the side street. Use square-foot values only in factory districts.

"Down-town Corners.—No rule can be applied successfully to down-town corner values. Each must be determined by itself on a square-foot basis, taking into consideration location, conditions, size, shape, and even occupancy. In large department stores, one square foot is practically as good as another, whether corner or inside, when considered as a whole."

As in the case of rules for long and short lots, every appraiser is not able to gather a great number of data, and must be guided to a certain extent by the work of those who have made extensive investigations. The results of work on corner lot values, however, are somewhat meager and contradictory, and it is advisable to study each individual problem and check, in as many ways as possible, the results obtained by the application of some rule or percentage. A corner lot is more valuable than an inside lot by reason of the increased accessibility, the better possibilities of utilization, and the additional light and air. Increased accessibility and availability include all such

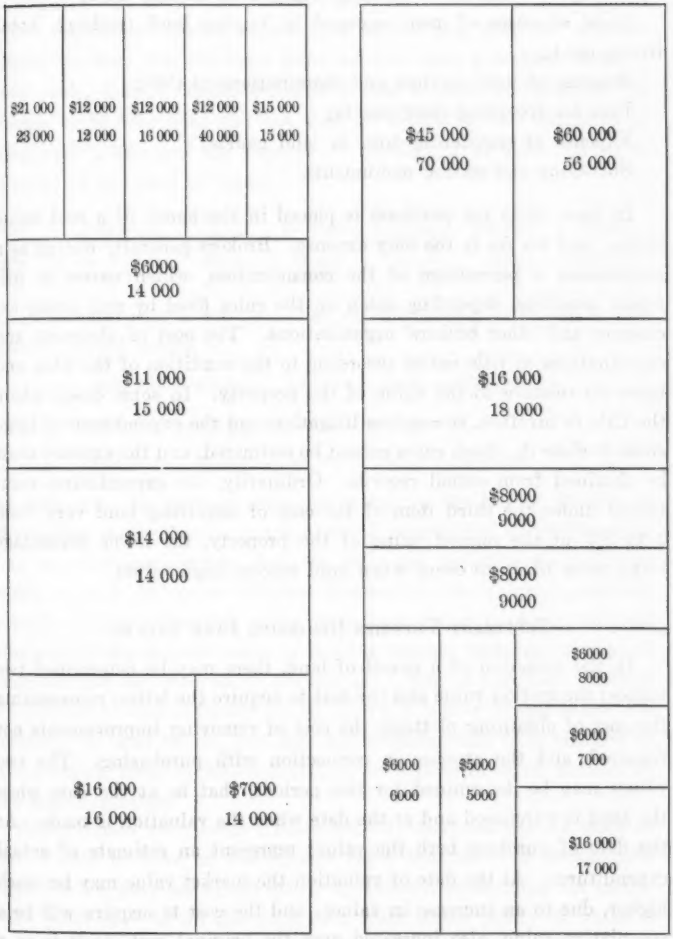
factors as greater facility of entrance to the property, added show-window and advertising space, increased amount of traffic at a corner, and the greater possibilities in designing buildings. If those advantages could be appraised and their value added to that of an inside lot, a check on corner lot values would be obtained.

In the case of business property, where all the factors mentioned must be considered, such a course is scarcely feasible; but it is practicable in simpler cases, such as occur in factory districts, where light and air are the only advantages to be gained by corner locations. The value of the advantage may be measured in such an instance by estimating how much vacant frontage would be required adjoining an inside lot in order to give it as much light and ventilation as the corner lot, and multiplying that frontage by the unit land value. If land has a market value of $400 per front foot and it is estimated that 22 ft. of vacant space would be required to give an inside lot as much light and air as the corner lot, then the sum to be added for this advantage would be 22×400, or $8 800. The estimated additional frontage, of course, should not exceed the width of the side street. This method is modified by a number of factors, such as the height of buildings, the shape and size of the lot under consideration, and the possible design of improvements as regards artificial lighting or the disposition of courts and light-wells.

As a rule, corner influence does not extend across ownership lines along the main street, and property adjoining a corner lot on the main street is of little higher value than any other inside frontage. Only in so far as it is located close enough to the corner to benefit by the increased street traffic there does it have any increased value whatever. Along the side street the corner influence generally extends beyond the corner lot, the value of frontage grading down regularly from the main street corner until the normal market value on the side street is reached. As light cannot be utilized more than 40 ft. from the lot line, the added value due to it should not attach to property more than that distance from the corner. Moreover, if the corner lot is narrow, the light advantage cannot be completely utilized, and is of less value. Corner values in residence property are of much less importance than in business property. In a district where each building is on a fair sized lot with plenty of space around it, the corner has practically no additional value beyond that which is due to the additional street im-

provements; but, in more crowded sections, where there are flats and apartment houses, the corner lot may be worth from 25 to 50% more than inside lots.

Many of the large real estate and appraisal offices have their own rules for handling questions of long and short lots and corner lots, and guard them carefully as office secrets. It is hardly possible that their private studies should yield information varying to any great extent from that which has been discussed herein, except in cases where it applies to peculiar local conditions. A number of the most difficult cases in determining land values are encountered in appraising corner lots. Every corner lot presents a different problem, and, after general rules have been applied, each case should be studied with regard to its peculiar features.



Plottage.—In certain classes of property, where several lots or blocks, or an unusually large frontage, are held under one ownership, a tract of land may have an additional value by reason of its being thus held. Where such conditions prevail, the tract is said to have plottage, and, where the land is more valuable by reason of such conditions, to have a plottage value. Although a piece of land may have an unusually large area, it does not have plottage value unless it can be occupied by some utility which requires an extra large site. If a tract of six or eight adjoining lots is available only for dwellings it will have to be broken up into single lots in order to be utilized, and consequently has no additional value; but, if it were owned by a traction company, and used for a car-barn site in a district where tracts of equal size were not readily available, it would have a plottage value. When a market value for such a tract has been determined, it is customary to add a percentage to cover the plottage value, and 10 and 15% are commonly used. Plottage value exists by reason of the fact that it is necessary to expend amounts in excess of market values in order to gather several adjoining pieces of land under one ownership, and some measure of the amount to be added for this value can be ascertained by estimating what additional expense would be incurred in gaining control of several adjoining properties held under separate ownership. In acquiring land, under such circumstances, it is not always possible to condemn, but it is possible to obtain options and get the proposition lined up so that the owner of one parcel cannot demand a prohibitive sum after money has been invested in several surrounding tracts. Even with careful buying,

however, the grantee is generally obliged to pay an exorbitant price for one or two lots in order to close a large deal. Such a transaction, however, is not made unless a considerable portion of the tract can be obtained at a reasonable market value, and though a double price may be paid for some pieces, the percentage above market value, computed on the entire purchase, is not apt to be excessive.

Fig. 4 is a diagram of a group of lots purchased by a large company for a home office building site, and is a fair example of the manner in which such a property is acquired. Twenty parcels of land were purchased, constituting an entire city block. On each parcel is shown the estimated market value and directly under it the sum paid out for that piece of land. The market value of the entire block was $302 000 and the total cost of acquiring the twenty parcels was $384 000. The excess over market value was $82 000 or 27%, but, nevertheless, the deal represented a very good piece of buying, and the total tract could be said to have a fair plottage value of $82 000. This instance is unusual, a much more frequent case being where three adjoining lots are worth $2 400 each and the plottage value for the three together is estimated at $800. Plottage value may be said to range from 10 to 25% of the market value, the percentage decreasing as the value of property increases, and increasing in proportion to the number of lots or parcels constituting the tract.

Cost of Acquiring Land.

Considered from a different viewpoint, plottage value is simply one of three items which may be called collectively "the cost of acquiring land", as it represents an amount in excess of market value which it is necessary to pay out in order to purchase several adjoining pieces of land. Another item of this group is the cost, in connection with purchasing land, of buying and removing buildings or other improvements which are on the land but are of no value to the purchaser. There are numerous cases in connection with land purchases where large and serviceable structures have been wrecked to make room for a different type of improvement, and, even considering the salvage, the expense involved is often considerable. This cost, of course, is subject to no regular influence, and must be determined under the conditions existing where it is encountered. The third item of the cost of acquiring land is the actual expense in connection with making the purchase, and composes one or more of the following sub-items:

Upper Figures=Market Value
Lower Figures=Purchase Price

FIG. 4.

Expense of searching for and choosing a site;

Salary or commission of men engaged in buying land;

Field expenses of men engaged in buying land (railway, hotel, livery, etc.);

Expense of legal services and examinations of title;

Fees for recording instruments;

Expense of registering title in land courts;

Surveying and setting monuments.

In most cases the purchase is placed in the hands of a real estate broker, and his fee is the only expense. Brokers generally charge as a commission a percentage of the consideration, which varies in different localities, depending often on the rules fixed by real estate exchanges and other brokers' organizations. The cost of abstracts and examinations of title varies according to the condition of the title, and bears no relation to the value of the property. In some cases, where the title is involved, it requires litigation and the expenditure of large sums to clear it. Such cases cannot be estimated, and the expense must be obtained from actual records. Ordinarily, the expenditures mentioned under the third item of the cost of acquiring land vary from 2 to 8% of the market value of the property, the lower percentage being more likely to occur when land reaches high values.

Different Theories Regarding Land Values.

In the valuation of a parcel of land, there may be determined two values: the market value and the cost to acquire the latter, representing the cost of obtaining plottage, the cost of removing improvements not required, and the expense in connection with purchasing. The two values may be determined for two periods, that is, at the date when the land is purchased and at the date when the valuation is made. At the date of purchase both the values represent an estimate of actual expenditures. At the date of valuation the market value may be much higher, due to an increase in values; and the cost to acquire will be a speculative value, also increased over the original cost, as it is to a large extent proportional to the market value.

Assume the history of a property to be as follows: Four lots having a market value of $3 000 each were purchased by a company for the sum of $14 900; buildings of no value to the company were purchased

and removed at a net cost of $4 700; and the expense of purchasing the property was $500. The total expenditure was $20 100, of which $12 000 represents market values and $8 100 the cost to acquire. Assume, further, that 20 years later the lots have a market value of $6 000 each; that a careful estimate of the amount to be added for plottage is $5 000; that the net cost of removing the buildings is placed at $11 000; and the expense of purchasing at $700. What is the value of the tract of land?

Date.	Property.	Market value.	Plottage.	Net cost of removing buildings.	Expense.	Total.
1896	4 lots.....	$12 000	$2 900	$4 700	$500	$20 100
1915	Same property..	24 000	5 000	11 000	700	40 700

The investment cost is $20 100. The capital charge (allowing for the increase in land value) is

$$\$24\,000 + \$2\,900 + \$4\,700 + \$500 = \$32\,100,$$

or, if the increase in plottage value is also included,

$$\$24\,000 + \$5\,000 + \$4\,700 + \$500 = \$34\,200.$$

The sale price to another company would be $24 000 + $5 000, or $29 000, but the replacement value would be $40 700. The foregoing is an extreme case, and is given to show the variation in valuation results, worked out under different theories or for different purposes. In public utility regulation cases, there is a strong tendency, in land valuation at the present time, to use the market value as of date of valuation, and add the cost to acquire as of date of purchase. This is in conformity with a theory which allows a utility to capitalize the increment in land values, but does not consider that it is entitled to an increment, more or less speculative, to expenditures in connection with land purchases.

Values Based on Special Utilization.—In frequent cases a tract of land is held to have an exceptional value because it is particularly adapted to the purposes of the utility by which it is occupied. A steam-power plant may be on the bank of a river where plenty of water is available for heating and condensing purposes, and the conditions may be such that no other site with equal facilities is to be had. The position often taken in such cases is that the location has a peculiar advantage for steam plant purposes, which it would not necessarily have for the purposes of a wholesale house, a railroad yard, or some

other utility; and, as a similar location cannot be obtained, it has a value in excess of the market value of adjoining lands. This additional value may be based on the extra cost of providing a tunnel from some other location to the river, or on the saving effected by the existing water supply over a well supply. A further step in this direction is to give land a value based on its highest utilization, even though such utilization has not been accomplished. A notable instance is the case of certain islands in the Upper Mississippi River which were taken for public use. The jury assessed their value as waste land, and, for any except boom purposes, at $300; but, in view of their adaptability for the formation of a boom across the river, at more than $9 000. The Court found the owner entitled to the larger sum, although the islands were not at the time, in fact, used for boom purposes, but were capable of such use. Instances of this kind are mostly encountered in land damage and land condemnation cases, and are based on the wording of the laws governing such cases, which state in brief that when a man's property is taken from him he shall be recompensed to the extent of its full value for its most valuable use. High values, in such instances as the steam plant location, however, are based on the theory of the cost of replacement of the property. In the majority of these situations, neither was the actual cost of the land excessive, nor could the land be sold to another utility for a high figure; and extra value is claimed simply because, if the power company did not own the site, it would require great expenditure to obtain one which would be as suitable.

The method of handling such cases depends on the theory under which the valuation is undertaken. If the basis of the work is "what would it cost us to replace this land if we did not own it", or "what expenditures would be entailed if we could not obtain it", it is easy to justify extreme values. Consideration should be given, however, to factors which sometimes modify these values. A small rocky island in a river may be said to be very valuable to a water-power company as an anchorage for a dam, but, in valuing the entire property of the company, the fact that a high value has been placed on a bit of waste land increases the theoretical cost of developing the water-power, and, when the value of water-power rights is computed, they will be found to have a lesser value to exactly the extent that the theoretical cost of development has been increased by placing a high value on the

island. Such an island may save many dollars to a railroad company as a footing for a bridge pier, but, if it has been necessary to change the grade or alignment of the road in order to cross the river at that point, the saving may be greatly reduced. Even though the island were directly in the path of the railroad line and could be utilized for a bridge foundation without any extra expenditure to make it available for that purpose, it is questionable whether the land would have any but a nominal value. The island is only a natural feature of the territory crossed by the railroad, and to claim a high value for it is akin to placing a higher value on railroad right of way in a level district than in a hilly one, where land has the same value for farm purposes, but where earthwork and curves make railroad construction and operation more expensive. It is evident that appraising land on the basis of its value for certain uses may be carried to absurdities.

To return to the case of the steam-power plant, previously cited: There are in every large community utilities which require facilities for coal and water supplies, and, if locations with such facilities are limited, the competition is bound to develop a stiff market value for land of that class. On the contrary, in situations where the plant is on land which, if not used for power-plant purposes, would be occupied by a utility which would not take advantage of the special facilities offered, the market value of the land should be based on that class of utilization. Sometimes a utility, in buying a piece of land particularly suited to its purposes, pays a large sum for it when no other utility is competing for the location, simply because the owner recognizes that the purchaser is especially desirous of obtaining it and holds to a figure above the market value. The utility may want the land because it has special facilities for coal and water supplies or because it adjoins land already owned, but in either case it is simply a circumstance that confronts the purchaser, and the market value of the land is not increased thereby. Generally, the sum paid for a piece of land having a special value to the purchaser is not excessive, due to the fact that the seller frequently considers the value from the viewpoint of his own utilization of it, and does not ask himself "what is it worth to the purchaser". A railroad company requiring earth for a large fill may acquire a particularly suitable piece of land at the market value, the seller having in mind only its value as farm land and not considering that the purchaser wants it for filling

material and would have a long haul if the material were obtained elsewhere. Under such conditions, the purpose for which property is wanted is concealed, and, where the identity of the purchaser would suggest it, the transfer is made through a third party.

In concluding this phase of land values it may be said that the cost of replacement as applied to land may lead to extreme results, and furthermore, it is a theory which is considered by many authorities to be unsound for most appraisal purposes. If a market value is to be determined for land which has special advantages for certain utilizations, it should not be abnormally high unless there is competition for the location based on its peculiar facilities.

Value of Railroad Land.—The valuation of railroad lands is a problem which has confronted appraisers in recent years. Such valuations are generally made by employing men familiar with land values, and they gather sales and other data regarding the value of land along the railroad right of way, and use the information collected, supplemented with personal opinions, assistance from real estate dealers, and notes from the company's records, to fix the values. Railroad lands are so extensive, and include so many grades of property, that an appraiser is not warranted in going into details to the extent that is customary in making ordinary land valuations. Not only would it be too laborious a procedure under most circumstances, but there would be little net gain in the accuracy of results. By using a rougher method, any individual tract of railroad land may be given a market value that is in error, but, if all inaccuracies are compensating, the net error throughout a State, or even in one city, is a very small percentage of the total value.

The method of using tax assessments which has been outlined heretofore is particularly applicable to the valuation of railroad lands. Maps are first provided showing the railroad lands and also the adjoining property for several blocks on each side of the right of way and terminal grounds. Owing to the nature of railroad lands, the units, such as lot values and front-foot values, cannot be readily applied, and it is necessary to use the value per square foot. In order to compare and apply the assessments on adjoining lands, they must be reduced to the square-foot unit, if they do not exist in that form in the public records. The assessments are recorded on the map, and the right of way is then inspected in the field in order to determine its relative value

as compared with adjoining lands. In the light of the inspection and the data recorded on the maps, the railroad lands are given an assessed value which is subsequently converted to market value by applying the ratio which has been found to exist in that particular district between market values and assessment values. The market value determined for any given piece of railroad land may be slightly incorrect, but the net result for a city is accurate, as no cumulative errors are introduced. This method may be used in either city or country districts, and is very convenient where good sales are scarce, which is generally the case.

Cost of Acquiring Railroad Land.—In acquiring railroad right of way, many expenditures are incurred in addition to paying the market value of the land purchased. Among the more important may be listed the following:

1.—Wages and commissions of men engaged in purchasing land;
2.—Field expenses, traveling, livery, board, etc., of men engaged in purchasing land;
3.—Printing and advertising, notices, etc.;
4.—Abstracts and examinations of title;
5.—Fees for filing and recording documents, etc.;
6.—Condemnation and legal expenses;
7.—Purchase of buildings, orchards, crops, etc., on land required for railroad purposes;
8.—Damages to adjoining property;
9.—In addition there are the amounts paid out which represent no value received or damage inflicted, but merely the sums which it is possible for land owners to extort from a railroad company under the conditions which prevail in buying railroad lands.

The first six items are small, and range from 4 to 12% of the total amount paid for land. The smaller percentage obtains in the case of a large railroad having a land department and a purchasing organization, and the larger percentages are found in the case of small electric lines acquiring only a few miles of right of way, and using only a temporary organization for the purpose. These items are of minor importance, however, and the cost of acquiring railroad land is determined chiefly by the magnitude of Items 7, 8, and 9. These three items are not

governed by any established laws or ratios, but are controlled to a certain extent by the following factors, and it is impossible to determine the extent of any one influence separately:

1.—Value of Land.—As the value of land increases, the proportional cost to acquire decreases. In buying cheap lands, the railroad companies do not make the effort in purchasing that is made in cities, where the investment is larger, nor are they so likely to resort to condemnation, for it is sometimes cheaper to pay five or ten times the market value of poor lands than to undertake the expense of condemnation.

2.—Ownership.—The class of ownership and the area of land under single ownerships is a factor. In some of the lumber States there are thousands of acres of cut-over timber lands held by single lumber companies, and it is possible to obtain large portions of a right of way at reasonable figures by dealing with only a few such land-holders.

3.—The extent to which a community is built up obviously affects the matter of damages in both city and country lands. In undeveloped territory, it is possible to buy land cheaper by reason of the fact that land-holders are desirous of obtaining railroad facilities. A new line through districts already well supplied with railroads, however, obtains no such favors.

4.—The direction of a railroad line has some effect on the extent of damages. A line running diagonally across the country cuts all farms into triangular pieces, but a right of way which parallels the section lines, preserves the shape of fields and causes less damage.

5.—One of the chief factors in the cost of acquiring railroad lands is the skill of the company's buyers. There are instances where right of way has cost a railroad company 50% more than it should have, owing to poor buying.

There are many other influences which are of a minor or local nature.

The only way to determine the cost to acquire a given strip of right of way is to learn from the company's records what was actually paid out in acquiring it and deduct from that sum the estimated market value of the land. Investigations of this kind show that the cost under

different conditions varies tremendously, ranging all the way from 5 to 600% of the market value. If it is necessary to make an estimate of this cost and no records are available, a study should be made of the results of purchases of railroad lands in near-by territory, under similar conditions to those affecting the right of way under consideration. If such a guide is not to be had, an estimate is largely guesswork. Although the variation is great, the average of the cost to acquire land for railroad purposes in a number of instances has been from 50 to 100% of the market value in cities and from 200 to 300% of the market value in country districts.

Cost of Land Appraisals.

The cost of making appraisals of property generally runs from one to two-tenths of 1%, and, as a rule, the work done on the land should not be more expensive than that on other classes of property in an inventory. Real estate men charge fees for appraising land which range as high as one-quarter of 1% for city property and one-half of 1% for suburban property. The cost of valuing the land of a utility should increase according to the number of scattered parcels to be handled, and should decrease in proportion to the increase in the value of lands to be appraised. It may easily require less effort to appraise a single parcel of land worth several hundred thousand dollars than to place a value on several parcels, the aggregate value of which is not nearly as great.

DISCUSSION

Mr. King.

W. I. KING,* ESQ. (by letter).—There is a dangerous and time-honored economic fallacy hidden in the sentence "The true value of land is the ground rent capitalized". After two thousand years of search for the "true value", economists are in agreement that no such thing exists. Furthermore, "ground rent capitalized", unless the phrase is broadly interpreted, gives no kind of value of any significance.

Every prospective buyer or seller of land has in mind a maximum price which he will pay or a minimum price which he will take. These subjective prices are finally based on the beliefs as to the probable future income which may be expected from the land. In other words, each person, using his own rate of interest, discounts these anticipated future rentals and finds their entire present worth. With their subjective prices in mind, bidders enter the market, and, by the well-known principles of supply and demand, fix the market price for the land.

At some periods, nearly every one becomes unduly optimistic as to the future outlook; at other times pessimism reigns. This change in the point of view of the majority causes land values to fluctuate widely on the market. If these values are plotted, it will be noticed, however, that there is a rather definite trend in a certain direction. This trend records values arising from the normal consensus of opinion, and may be said to represent normal land values; but value is always based on anticipation, and, until the veil is rent from the future, no man will ever be able to state correctly that any figure represents the true value of the land.

In a progressive community, land values usually stand well above the capitalized present net rentals, because people do not expect that rentals will remain constant, but rather that they will rise. To correct for this error by varying the rate of interest used in capitalizing the current rent is, at the best, a very crude method of adjustment. The writer has described, in "The Valuation of Urban Realty for Purposes of Taxation",† ways of solving the problem which appear to be more logical.

The writer notes, also, an apparent misconception of the word "economic" as used on page 586. The demand of wealthy persons for pleasant residence sites is certainly as strictly economic as the demand of a railway for a site for a new depot or roundhouse.

Mr. Jerrard's discussion of such topics as the movement of the business section, "plottage", "cost of acquiring land", and "values based on special utilization", is both able and interesting, and appears to be better developed than any writings on the subject which the writer has previously read. The author is to be congratulated on the scientific and scholarly nature of the paper as a whole.

† *Bulletin No. 689* of the University of Wisconsin. May be obtained from the Librarian of the University.

Mr. Kelly.

HUGH A. KELLY,* ASSOC. M. AM. SOC. C. E.—This paper is a valuable addition to our records. The speaker, being in constant touch with the Taxing Department of Jersey City, has become familiar with the question of "land valuation", and when he read this paper he realized that it was practically flawless. In order to be sure, however, he handed it to the two men whom he thought best qualified to judge: Mr. J. Stewart Walker, formerly Chief Engineer of the Jersey City Map Department, and Mr. Raymond C. Buckley, the present Chief.

Jersey City issued last year a manual for the guidance of the working force in the Bureau of Tax Assessment of the Department of Revenue and Finance. This "Assessors' Manual", the first issued by any city in the United States, was written by these gentlemen, under the direction of Commissioner George F. Brensinger, and after reading Mr. Jerrard's paper, they also agreed that he has left little to discuss. Nevertheless, the following few points may be well taken.

If one examines cases of tax appeal one will find that the real estate man must have his builder, his architect, to support him. In the more important cases, such as railroad cases, it is the engineer who knows real estate who is called on to testify. In a town the speaker has in mind he knows of but two real estate men who have carefully compiled their sales and put them in proper form for immediate use in appeal cases.

This only emphasizes Mr. Jerrard's contention that the engineer should check the real estate man, and verifies the statement that the average real estate dealer's appraisal is but a look, a thought, an interview, and an opinion.

The author states:

"The ground rent is the net income which remains after paying the taxes on the land and the taxes, depreciation, interest, and maintenance on all improvements."

To this list of deductions there should be added the item "a sinking-fund charge sufficient, when put at interest, to cover the cost of the building in a given number of years".

How many real estate men include this item for their clients when presenting cases?

The author states that "the true value of land is the ground rent capitalized".

First: True value is spoken of by Judge Charles C. Black, in his book on "Taxation" in which he reviews many judicial decisions, thus:

"True value, like fraud, is incapable of definition, for the reason that no definition can have universal application to all the many classes of property."

He concludes with the statement:

* Jersey City, N. J.

Mr. Kelly.

"So the 'true value' of property, under the constitution for taxation, comes back in all cases to what such property will exchange for in the open market, in money. Sometimes cost is a fair criterion; earning capacity may be; frequently both should have weight; while, again, neither will determine its 'true value'; but all these elements of value should be considered."

Second: If one wishes to calculate the value of land from an income basis, one must select adequately improved property. Then if one adds to the present worth of all future anticipated net rentals of a new building, the present worth of the land value at the date when the building will need to be replaced, and deduct from the sum the cost of the building, it should closely approximate the present true value of the site.*

However, as new buildings exactly adapted to their location are rarely found, and the difficulties with this method are considerable, the sales method is to be preferred to the commercial method of finding the value.

Rarely is there an appraisal of property in which a true capitalization method is used.

In the report of the Morris Canal Investigation Committee, appointed by the joint Legislature of New Jersey, Louis Focht, Assoc. M. Am. Soc. C. E., Engineer of State Board of Taxation, uses such a method.

He projects a possible development, assuming 2 050 ft. of bulkhead, two piers 150 ft. wide, about 2 060 lin. ft. in all. On each pier will be placed one-story steel sheds 1 175 by 113 ft. and 1 250 by 140 ft., respectively; also a six-story warehouse covering an area of 83 000 sq. ft., together with the necessary tracks, filling back of bulkhead, dredging of slips, etc.

"The commercial value has been based on the capitalization of the net surplus after deducting the probable annual fixed charges from the probable annual income.

"The annual fixed charges are made up of the interest on the investment, an annuity sufficient to create a sinking fund for the purpose of extinguishing the debt against the perishable portion of the property at the termination of its probable life; taxes on the property, annual charge for dredging slips to maintain a sufficient depth of water; insurance on the portion of the property likely to be destroyed by fire; current annual repairs; and superintendence.

"These elements will now be considered in their order:

"First: In arriving at the value of the probable annual income, rentals of dock property in the harbor have been considered. They are lower on the New Jersey than on the New York side, and range about as follows:

New Jersey side of harbor.....	$0.32 to $0.40 per sq. ft.
New York side of harbor.....	0.20 to 1.54 per sq. ft.
Average.....	0.87 per sq. ft.

* King on "Valuation of Urban Property."

"Brooklyn rental, private piers, range from $0.48 to $0.57 per sq. ft. Warehousing rates range from about $0.25 to $0.30 per sq. ft. of floor surface. Mr. Kelly.

"In estimating the probable income, a rate of $0.50 per sq. ft. has been assumed for dock property, and $0.25 per sq. ft. of floor surface for the warehouse. On this basis, the following result is obtained:

PROBABLE ANNUAL INCOME.

Docking, 309 000 sq. ft. at $0.50 per sq. ft.	$154 500
Warehouse floor area, 498 000 sq. ft. at $0.25 per sq. ft.	124 500
"Total annual income	$279 000

"Other minor sources of income might be added, but, for the sake of conservatism, they have not been considered.

"The rate of $0.50 per sq. ft. is higher than the average New Jersey rentals, the development being of a higher character than other leased properties on the New Jersey side.

"An estimate of the probable cost of the development has been made, in order to arrive at the fixed charges.

"The estimated cost of the entire development for the 'Small Basin' is $2 265 000.

"In determining the annuity to be set aside for the sinking fund, an assumed life had to be given to each depreciable portion of the plant. These values will vary with the character of the structure. Considering an interest rate of 3½% on the sinking fund, the annuities in Table 3 are obtained.

TABLE 3.

	Life.	Per thousand.	On:	
Bulkhead	50 years	$7.63	$153 750	$1 173
Piers	40 "	11.83	618 000	7 311
Sheds on piers	40 "	11.83	400 000	4 732
Warehouse	50 "	7.63	755 300	5 763
Paving	15 "	51.82	9 750	505
Gantry cranes	15 "	51.82	30 000	1 555
Tracks	15 "	51.82	37 811	1 959
Totals			$2 004 611	$22 998

TABLE 4.—ANNUAL CHARGES.

Interest on $2 265 000 at 5%	$113 250
Annuity for sinking fund on $2 004 611, at 3½% (average)	22 998
Taxes on $1 698 750 at $2.00 per hundred	33 975
Annual charge for dredging slips to maintain constant depth of water, 20 000 cu. yd. at $0.20	4 000
Insurance on $1 800 000 of dock property, at 0.5 of 1%	9 000
Current annual repairs	15 000
Superintendence	5 000
Total fixed annual charges	$203 223

Mr. Kelly.

"In the computation of the annuities in Table 3, it will be noticed that there is no item for grading or other permanent work, which, when once completed, would last indefinitely.

"On the foregoing basis, therefore, the statement in Table 4 will represent the entire annual charges.

"With the fixed annual charges shown in Table 4, the net surplus will be:

Total annual income	$279 000
Annual fixed charges	203 223
Balance, or annual net surplus	$75 777

"Therefore, if the present worth of this net surplus, namely, $75 777, is computed on the basis of 5% interest for a term of 60 years, or the limit of the period when the canal will revert to the State, a value of $1 434 459 is obtained for the land."

The author (page 585) states as follows: "advantages of location govern the values entirely". The last word of this statement is open to question. The "Assessors Manual" quotes Mr. Alfred D. Bernard of the U. S. Fidelity and Guaranty Company, thus:

"We therefore announce four cardinal factors of value in real estate:

"1—Location, which includes access;
2—Utility, which includes capacity to produce;
3—Shape;
4—Size."

These are explained as follows:

"(1) Location.—In any city the most valuable corner lot would appear to be the lot in that city accessible to the most people.

"Now, if that proposition is sound, the most valuable corner lot is the center of population of any given city.

"In the City of Baltimore, the center of population is in the colored belt, at a point where land values are around fifty cents a square foot; so, in fixing the most valuable corner lot we must assume something else besides accessibility of location; we must assume the second factor, utility.

"(2) The highest utility which land may assume, generally speaking, is retail business, and the student of values will find that, with the exception of the banking district of New York City, the highest valued properties in all the cities may be found in the retail business districts.

"Now, with Factors 1 and 2 to resolve, we find the most valuable corner lot in any city is that lot which is so located as to be accessible to the greatest number of people who buy goods.

"After fixing the point, we must then consider the reason why one lot is more valuable than another, which calls upon us to invoke the other principles, of shape and size. The most desirably located corner may be too small to meet the business demand, and the business be carried to the next block, or, by reason of angles and irregularities,

it might not be available for the business of the territory, and thus lose in contrast with other regular lots." Mr. Kelly.

From the foregoing it is evident that the greatest number of people necessarily do not pass through the heart of the city, as Mr. Jerrard states, but more generally the greatest number of people pass near some railroad terminal or boat landing.

The retail section moves in the direction of the best residence section. Bernard sees it as follows:

"To-day the most valuable block in a given city is Main Street between X and Y Streets. Thomas Tenant's lease is about to expire. He has made big money in the twenty years he has engaged in the dry goods business in this block. His landlord wants to share his business with him and doubles his rent. Tom has made money and saved it, and feels independent enough to tell his landlord to go where ice is popular but scarce; but the landlord doesn't melt, and Tom has to pay double the rent or move. The district broker whom Tom employs to buy the site is met with 'Not for Sale', and tells Tom about four little shacks he can buy in the second block north of him and build his own building and laugh at the landlord. He does it. He builds a fine warehouse, better than the one he was in, advertises to the trade that he was forced out of his old location, and thus wins sympathy and trade. He is followed by another unfortunate, and in three years the best block on Main Street is Tom Tenant's block."

Mr. Jerrard states that the total land value of a city depends primarily on the population, but is influenced by wealth.

Bernard says:

"While the proposition may be new and startling, the writer's study of land values in cities warrants him in asserting that land values bear a relation to the number of and buying power of the inhabitants of a given community, and that in the average normal city the value of the retail business property is one cent per foot front per person and the best residence property 1/10 to 1/12 of a cent per foot per person."

In answer to the disadvantage of using gross rentals, Bernard uses such rentals, and gives, as the advantage, the fact that it eliminates the item of poor management, which invariably brings down the net rental.

If the value of the improvement is 9 times the value of the site, the gross rental should be 19% of the total investment,

8	times	the	value	of	the	site	18%
7	"	"	"	"	"	"	17%
6	"	"	"	"	"	"	16%
5	"	"	"	"	"	"	15%
4	"	"	"	"	"	"	14%
3	"	"	"	"	"	"	13%
2	"	"	"	"	"	"	12%

Mr. Kelly.

Improvement and site equal (for office building only) 10 to 12 per cent.

To Mr. W. A. Somers is attributed the statement that the corner influence in all property generally extends 100 ft. each way from the corner. The literature of the Manufacturers Appraisal Company contained this statement, but that company acknowledged this to be an error. The speaker thinks it is an exceptional case where corner influence extends more than 25 ft. beyond the corner.

The value of lots of various depths, expressed as percentages of unit value, or "rules for long and short lots", as it is termed, requires the attention of a mathematician.

The speaker believes that Mr. Davies is the only man who gives a formula with his rule, and states that the curve is a parabola.

Interpolation, to determine intermediate values, is not satisfactory where many properties are handled. In the Jersey City Tax Office, to facilitate matters, the engineers in the Map Department have an equation for the Hoffman rule, which is in the Tax Manual published by the Department of Revenue and Finance of that city.

It is stated that Mr. Davies examined 10 000 sales. Mr. Bernard, Mr. Somers, and all the others examined many sales in order to derive their curves of values.

There is a question in the speaker's mind whether a man can be so familiar with every one of 10 000 sales as to be able to squeeze out all the influences that would pull them away from normal. Probably the law of averages would counteract errors in so great a number of sales.

The problem of depth and value presents an example resulting in an equation the curve of which, when plotted, is that of a conic section. The Hoffman rule works out as a parabola.

Knowing these results, why is it not as good to assume a condition, as Hoffman did, and work out the equation; or why not take the least number of sales or points that will determine a conic curve, and if the curve suits our judgment, adopt it.

If all the values in a curve do not respond to some formula, the speaker claims that the curve is theoretically incorrect, as no two persons are treated according to the same law.

Would it surprise the author to know that Hoffman's opinion, in 1870, agrees with Bernard's careful investigation, in 1913? If Mr. Jerrard's conversion of the Bernard 150-ft. to 100-ft. rule is correct, such is the case. Unfortunately, Hoffman's complete figures are not given in Table 2. In Table 5 is given a comparison of Hoffman's and Bernard's figures. In no case is there a difference greater than 1 per cent.

In the author's comparison of the rules, it will be noticed that, up to 100 ft., the Newark business is the same as the Somers. The

Newark residence, up to 100 ft., is practically the same as the Hoffman. There is a close resemblance, up to 100 ft., of Milwaukee business and Somers, and for more than 100 ft. they agree. For more than 100 ft. Newark business and residence agree. Mr. Kelly.

80	91	91
85	93.5	93
90	96	95
95	98	98
100	100	100

Such peculiarities would lead one to suppose that some of the rules represent no independent investigations.

In Table 6 the speaker examines the Hoffman rule by subtracting the value of every 10 ft.—ten lower from ten higher—thus 10 ft. = 25%; 20 ft. = 41%; 41 — 25 = 16, etc. This gives a series of percentages or first differences.

TABLE 6.—Examination of the Hoffman Rule.

Feet.	Percentage.	First differences.	Subtract.	Second differences.

80	91			
		5	10	— 5
90	96			
		4	10	— 6
100	100			

Mr. Kelly.

If 10 is subtracted from each of these we get a series of second differences in which it will be noted that 4 is lacking.

The original Hoffman rule does not plot as a smooth curve, but if 4 is supplied in this last series of numbers the following formula may be derived.

Assuming that 50 ft. gives 66⅔%, the formula is:

$$y = \frac{2x}{3} - \frac{x}{150}.$$

If 50 ft. is assumed to give 67%, the formula is:

$$y = 1.68x - 0.0068x,$$

which gives a true parabolic curve.

These formulas were derived by Mr. Walker. This peculiar condition leads to the belief that some real estate men do not understand these rules thoroughly; for, in important cases, where large tracts of land are involved, we find them analyzed by real estate men thus:

Zone 1, so many feet deep, parallel with the street, is worth a dollars. Zone 2, directly behind it, is worth b dollars, etc.

But Zone 1 reflects its value to Zone 2, etc., and immediately the straight-line valuation begins to bend, and, the smaller the zones are divided, the greater becomes the reflected increments, until the straight-line valuation becomes some kind of a curve.

The speaker believes that these rules for short and long lots are the final result of this line of reasoning, and the foregoing examination of the Hoffman rule proves it.

The appraisal of lands in different localities and sections requires individual attention and study, and for these no rules can be laid down which will fit all cases. Mr. Jerrard's paper gives a firm foundation on which to build.

Mr. Rankin

EDWARD S. RANKIN,* M. AM. SOC. C. E.—This discussion refers to the following statement in the paper:

"The total land value of a city depends primarily on the population, but is influenced to so great an extent by the city's wealth and other factors that comparisons between cities of the same population, as to either the total land value or the value of highest priced land, offer considerable variation. It is believed that the range of values in Fig. 2 will cover the conditions in all except a very small percentage of cities."

In an attempt to formulate the relation between the population and land values in cities, the speaker some years ago addressed letters to real estate dealers in the 109 cities of the United States having a population of 50 000 or more, asking the value per front foot of

* Newark, N. J.

the highest priced land in their respective cities, based on a standard lot 25 by 100 ft., exclusive of corners. Replies were received from 47 cities, the smallest being Canton, Ohio, with 50 200, and the largest, St. Louis, with 687 000 population (census of 1910). Mr. Rankin.

The results obtained, though of a negative character, may prove of some interest in connection with this paper. They have been plotted on a diagram, Fig. 5, similar to Fig. 2, and seem to show the hopelessness of attempting to base valuations on population, except in the most general way. It would appear, however, that the curves in Fig. 5 are entirely too low.

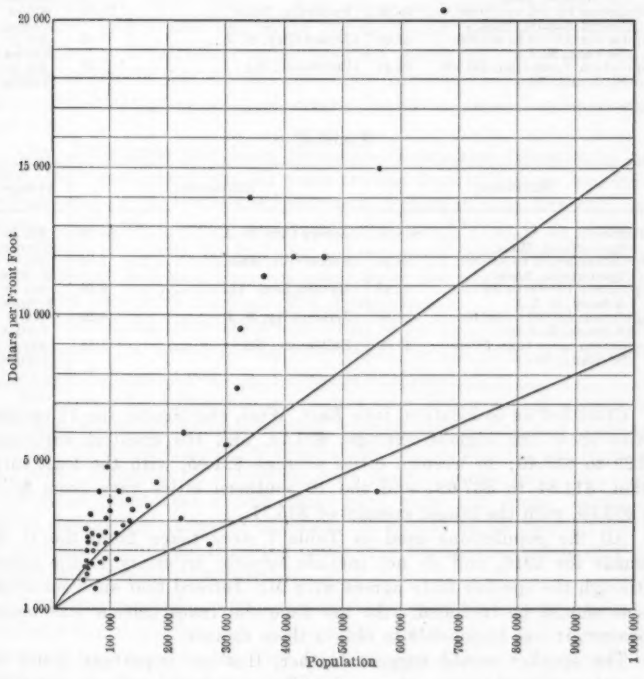

FIG. 5.

Reduced to dollars per front foot per 1 000 population, the variations are perhaps even more apparent. Some of the main features of the investigation, reduced to this basis, are shown in Tables 7 and 8.

Believing that the rate of growth of the city would have a decided bearing on the valuations—on the principle that values would discount the future—the speaker then made an estimate of the probable popu-

Mr. Rankin.

lation of each of the cities in 1920, and calculated the value per front foot per 1 000 of this estimated population. The results are given in Table 8, and show slightly less variation, but are still too far apart to be of any practical value.

TABLE 7.

Maximum.		Minimum.		Average.
All cities	$54.00	(Baltimore, Md.)	$7.16	$27.86
(Springfield, Mass.)				47 cities.
Population 50 000 to 100 000	54.00	(Somerville, Mass.)	9.71	$30.85
(Springfield, Mass.)				24 cities.
Population 100 000 to 200 000	35.52	(Nashville, Tenn.)	15.80	$26.64
(Grand Rapids, Mich.)				10 cities.
Population 200 000 to 400 000	40.28	(Jersey City, N. J.)	8.06	$23.12
(Newark, N. J.)				8 cities.
Population more than 400 000	29.48	(Baltimore, Md.)	7.16	$23.59
(St. Louis, Mo.)				5 cities.

TABLE 8.

Maximum.		Minimum.		Average.
All cities	$38.40	(Jersey City, N. J.)	$6.29	$20.33
(Springfield, Mass.)				47 cities.
Population 50 000 to 100 000	38.40	(Somerville, Mass.)	7.65	$21.33
(Springfield, Mass.)				24 cities.
Population 100 000 to 200 000	31.13	(Birmingham, Ala.)	9.00	$20.29
(Albany, N. Y.)				10 cities.
Population 200 000 to 400 000	28.86	(Jersey City, N. J.)	6.29	$18.77
(Newark, N. J.)				8 cities.
Population more than 400 000	25.00	(Baltimore, Md.)	6.78	$18.10
(St. Louis, Mo.)				5 cities.

Classified as to location, into East, West, and South, the 17 eastern cities show the highest average, $21.75, and the greatest variation, $6.29 to $38.40; 20 western cities average $21.45, with the least variation, $11.84 to $37.62; and the 10 southern cities vary from $6.78 to $23.69, with the lowest average of $15.71.

All the populations used in Table 7 were taken from the U. S. Census for 1910, and do not include suburbs tributary to the cities, although the speaker fully agrees with Mr. Jerrard that such suburban areas should be included. At the time the investigation was made, however, it was impossible to obtain these figures.

The speaker would suggest further, that an important factor in the value of land is the volume of traffic passing the point in question. A careful investigation along this line might prove of considerable interest.

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—Two interesting examples of the valuation of land in New York City, might be cited: First, the corner of Wall and Nassau Streets; a lot, about 25 by 75 ft., was bought

* New York City.

in 1896 for $500,000, and, after the old building had been torn down, a 17-story building was erected on the site at a cost of $1 000 000, making the cost of the new building and lot $1 500 000. The Bankers Trust Company, 14 years later, wanted the corner to complete its property in order to have about 90 ft. front on each street, so the 17-story building and lot was bought for $1 500 000 and then $50 000 was paid to a wrecker to remove the building quickly. Mr. Thomson.

The second case is that of a young man who had an assured income of $25 000 a year; he painted a little, wrote a little, and tried to make himself generally useful, and at the same time was able to live comfortably on his income. An uncle bequeathed him a $1 000 000 piece of property on West Street. Just then, unfortunately, the tenant moved out, and a new one could not be found, and as the property was subject to a mortgage which required nearly all the young man's $25 000 income to pay, he was absolutely impoverished by the bequest of a $1 000 000 piece of real estate, which he could neither rent nor sell.

One of the great stumbling blocks in modern real estate is the old 25-ft. front lot, which was all right in the days of one- or two-story cottages and stores, but is absolutely out of place in a modern city, and is responsible for much of our "crazy quilt work". It is to be hoped that future cities will be laid out on up-to-date lines, giving a whole block for each building, then the question of the relative values of the inside and outside of the block will disappear.

An interesting case occurred some years ago, when the caisson foundations of a new building encroached on the adjoining property at depths of from 30 to 90 ft. below the surface.

Mr. Jerrard's admirable paper has one defect which should be remedied before the final publication, thereby obliterating this comment thereon. It is the impression received by the reader that the engineer is a better authority on real estate than the real estate man. No engineer would grant that a real estate man, pure and simple, could do better engineering than the engineer. It should be an easy matter to remove this slight flaw from the paper, and the speaker trusts that the author will make this correction.

J. S. WALKER,* ESQ.—The speaker, until lately, has been connected with the Tax Department of Jersey City, and in his position witnessed many contests between the City and the corporations. In connection therewith he has heard able men discuss the various phases of this question. He realizes the fact that this paper represents a great deal of study, is to the point, and is correct. Mr. Walker.

The most interesting feature is the theory of the value of the fractional part of a lot. As Mr. Kelly has stated, Hoffman's opinion,

* Jersey City, N. J.

Mr. Walker.

in 1870, was that the front half of a lot was worth two-thirds of its total value. Hoffman produces a series of numbers; as to how he derived them we are not told, but they happen to be a series representing a conic section.

The conversion of Mr. Bernard's 150-ft. rule into the 100-ft. rule by Mr. Jerrard, agrees with the Hoffman Rule, which the speaker thinks is very peculiar.

The little investigating the speaker has done tends to show that the problem of the relation of depth to value results in an equation of the second degree, between two variables, and is an equation of a conic section.

In practice a curve is constructed or adopted, and, under certain conditions if it gives too much or not enough value, some other curve is copied in whole or in part. The curve then varies in such a manner that it cannot be represented by a formula. Such being the case, no two conditions are treated according to the same law.

A case in point is that of a district in transition from one use to another, such as apartments taking the place of private dwellings, the appraiser claiming that more value is found to a greater depth for land on which was built apartments than that devoted to private dwellings, and a variation of the curve in use was applied.

In 1912, or about that time, Newark had curves which differed from those in use at present, to which the foregoing objections would apply. The subject calls for extended and exact study.

The Manufacturers Appraisal Company, of Cleveland, Ohio, which uses the "Somers Unit System of Realty Valuation", does not reveal the method of calculating the value of corner lots, irregular lots, or reflected influences. It appears that a city hires only the use of the system, and, should it be desired to re-adjust values, it would be necessary to re-hire the system. Nevertheless, all things about the Somers System are not kept secret, and it has many good features.

First of all, it is a system that is carefully worked out. The speaker thinks it overcomes some of the objections referred to by one of the speakers.

A booklet, published by the City of Cleveland, Ohio, entitled "The First Quadrennial Assessment, Cleveland, Ohio", shows how Cleveland was assessed by the Somers System in 1910, and gives many details and charts.

Mr. W. I. King,* appears to have gotten nearer to the heart of the system than any one else, and shows some of the Somers charts not found elsewhere, but he says:

"Since the scientific accuracy of the Somers tables is not proven, and since these tables and their derivation are shrouded in secrecy,

* *Bulletin No. 689* of the University of Wisconsin entitled "The Assessment of Urban Property."

it seems necessary to derive a method of corner valuation, and ultimately a series of charts, which may lay some claim to a scientific basis, and at the same time, accord with actual conditions." Mr. Walker.

This bulletin is of value to those interested in taxation.

In assessment work, Mr. Somers lays much stress on the value of community opinion. He writes as follows with reference to an assessment in Des Moines, Iowa:*

"The first public meeting was held; * * * about seventy-five prominent citizens were present, including a majority of the largest property owners. After the session a committee of citizens and property owners was selected by the Mayor and Assessor to co-operate with, and assess the latter.

"At the outset it was decided to avoid discussion of actual values at first and to deal with relative values only. Therefore the efforts of the Committee were devoted to expressing in percentage the relative values of a Somers unit foot on each side of every block.

"It was the unanimous opinion that the most valuable frontage in the city was on the north side of West Walnut Street between Sixth and Seventh Streets. This the Committee called x, or 100 per cent. Then, at the several meetings, the relative value of a unit foot in every block throughout the West Side was ascertained.

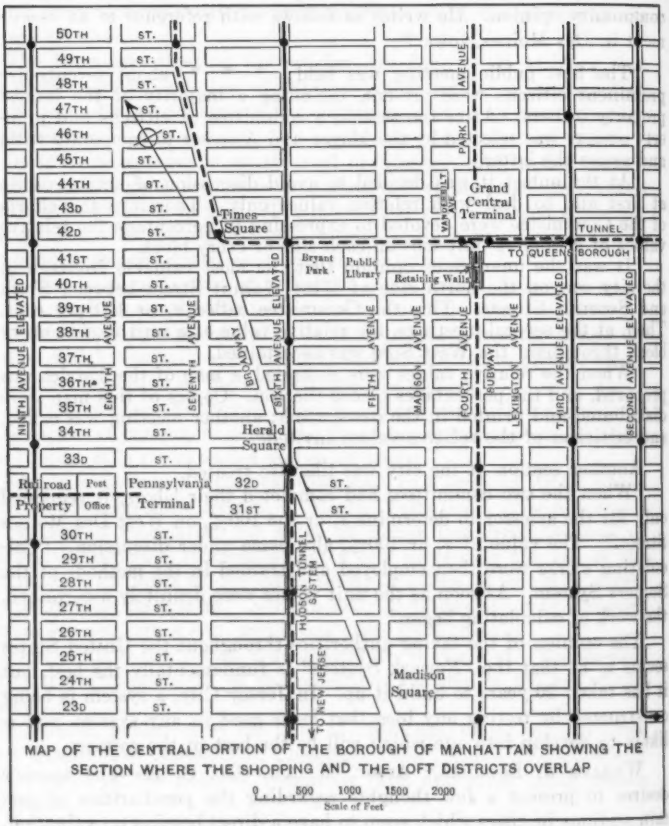
"When the relative values were compiled, a map of the district was prepared, and the percentages placed thereon. Copies of this map were distributed and printed in the newspapers; another meeting was called, and criticism of the relative values invited."

Another section of the city was likewise treated.

"When the two committees had completed their labors, it remained only for the assessor to determine x, or the 100%, on West Des Moines Street." The value of x, or 100%, also came under discussion. "Calculating clerks were then employed and trained in the methods of the Somers System. As soon as the unit values were definitely ascertained, the work of calculating began."

The opinion of the taxing authorities throughout the United States seems to be that the "Newark System" is fundamentally the best, but it has taken 20 years to build it up. In Jersey City, a system is being constructed by testing any idea that looks good in any system, and is likely to develop into one which will be the best in the country.

WILLIAM J. BOUCHER,† ASSOC. M. AM. SOC. C. E.—The speaker desires to present a few thoughts regarding the peculiarities of certain sections in cities which seem to have a direct bearing on valuation. Mr. Boucher.



One of the busiest retail business streets in Manhattan (New York City) is 42d Street, and every day, including Sundays, its sidewalks are filled with pedestrians and the roadway with cars and vehicles. Between Fourth and Eighth Avenues, during the past 10 years, there

* As published in the June, 1913, issue of the *Somers System News*.

† Long Island City, N. Y.

Mr. Boucher.

have been erected several high-grade office buildings, one first-class department store, numerous smaller stores, some excellent hotels and restaurants, several banks, the Central Public Library, and the New York Central Terminal Station. All these tend to make this one of the most popular and attractive streets in the city, and the rentals,

MAP OF THE CENTRAL PORTION OF THE BOROUGH OF MANHATTAN SHOWING THE SECTION WHERE THE SHOPPING AND THE LOFT DISTRICTS OVERLAP

FIG. 6.

and consequently the valuations, are high. Contrast it with 41st Street (Fig. 6), only 200 ft. away and parallel with it. True, it is not a through street, but though this affects vehicular traffic, it is strange that the street contains so little to attract the pedestrian. In the 400 ft. between Madison and Fifth Avenues, there is only one

high-grade office building. This has a frontage of 50 ft., is 100 ft. deep, and 20 stories high. It enjoys close contact with the Rapid Transit Subway, as one has merely to cross the street and enter the building on the opposite side, which has a subway entrance on its 42d Street front. The remainder of the block is occupied with small shops, restaurants for light, noon-day refreshments, and other establishments paying small rents. Mr. Boucher.

Again, consider 43d Street, which is 200 ft. to the north of 42d Street. It is a thoroughfare from the Grand Central Station to the Hudson River, but it has practically no retail, or other business to make large rentals or valuations. It is given over largely to clubs and other buildings where gatherings can be accommodated. One office building fronting on 42d Street, with a subway entrance in front of its door, has an "Annex" building on 43d Street. The buildings are connected by a through corridor giving the "Annex" the full privileges and benefits of the 42d Street entrance, but the rentals are considerably less than those for the 42d Street front. The contrasts of these two contiguous streets (41st and 43d), so close to 42d Street, form an interesting study.

Reference is made in the paper to the advantages of transportation, and it does seem as though that is the originating feature of value of land, although the speaker makes no claim to being an expert. One location stands out prominently, *viz.*, 149th Street and Third Avenue, and vicinity, in the Borough of the Bronx, which is a goodly distance from "down town", yet, through the influence of good transit facilities (both "Subway" and "Elevated", as well as surface cars), there has grown up in that section in the 12 years since the subway was opened to traffic, a very busy retail business center, where rentals must be quite high. Comparing this location, about 5½ miles from 42d Street, with its good transit facilities, with another location only about 1½ miles from the Grand Central Station, which has until recently had only the poorest, or practically no, transit, and the contrast is remarkable. This other location is in the Borough of Queens, directly across from 42d Street. It is true, it is separated from Manhattan by the East River and, until recently, that stream formed a most effectual barrier to progress. Two ferries, one at 34th and another at 92d Street, gave occasional access across, and brave was the pioneer who had his home or his business there. About 10 years ago, surface car service was established over the Queensboro Bridge from 59th Street, Manhattan, to Queens, but not until the Steinway or Queensboro Subway was opened, in June, 1915, with its free transfer privilege to the main subway line, could it be said that rapid transit existed there.

On the river front opposite Manhattan, from 45th to 59th Streets, there still remain large tracts suitable for wharves and warehouses,

Mr. Boucher.

and, farther inland, there are other large tracts, with railroad facilities, and now served with rapid transit, simply waiting to be developed with industrial establishments of every kind, with desirable locations for workingmen's homes near-by. These tracts may be had on very favorable terms, and the valuations are low when compared with other localities much farther removed from the business centers of Manhattan.

It is very unfortunate that real estate in the Borough of Manhattan, which, for so many years, has been considered a safe and desirable investment, should have proved so unstable and shifty in the past 10 or 15 years. Since the advent of the modern, steel skeleton building, with its cheap curtain walls and concrete floors, it has offered peculiar inducements for the manufacture of garments of white goods and clothing, in which lines large numbers of men and women are employed. This line of manufacturing, until quite recently, was conducted in the district south of 14th Street, in buildings of the old type so common all through that section. About 10 years ago, many progressive, but unfortunately, as it proved, misguided owners or speculators seized upon the section north of 14th Street, and, in practically every east and west street, erected many of the so-called "modern loft" buildings of ten and twelve stories, in which these garment trades are housed. The thousands of operatives are mainly recruited from the recently arrived immigrants, and, during the noon hour and at opening and closing hours, the sidewalks and streets literally are covered with the slow-moving, jostling, noisy swarms. At the time this movement of these trades was taking place, an entirely different movement was under way. The department stores which, 15 years ago, were on 14th Street and on Sixth Avenue, north of 14th Street, and on 23d Street, began to move to newer and more commodious quarters in the vicinity of 33d and 34th Streets, Sixth Avenue, and Broadway, and a little later to Fifth Avenue, north from 34th Street. Thus, the new "loft" district and department store district overlapped and conflicted to such an extent that the very existence of the department stores was threatened by the swarms of noon-day loiterers from the "lofts", who slowly wandered up and down and along, completely blocking the passage of would-be patrons of the stores.

The nuisance was so great that the "Save New York" movement has become a reality, and is already bearing fruit. The first result was the legal zoning of the city, during 1916, by which the character of various districts will be restricted, and in the different "zones" certain restrictions will apply, which will prevent the intrusion of businesses or trades into districts which would have their real estate values impaired or ruined by such intrusion. The "Save New York" move-

ment is considerably different from the zoning plan in that it involves a drastic remedy for existing evils in the district bounded by 32d Street (north side) to 59th Street, and from Third to Seventh Avenue. In brief, the scheme of the Committee was: To persuade manufacturers who contemplated moving into this zone to stay out; to induce those manufacturers already in, to move out; and to stop the erection of new manufacturing "lofts" in the zone bounded as described. An agreement was also made by buyers, to give the preference in buying goods to those concerns who do not manufacture in this zone, this measure to take effect on February 1st, 1917. The response to the Committee's appeal was immediate, and up to January 1st, 1917, the following results have been accomplished: First, not a single new lease for manufacturing purposes has been made in the zone; second, not a single new building for manufacturing purposes has been erected in the zone; and third, all but 20 firms, out of a total of 225 now manufacturing in the zone, have agreed to move out at the expiration of their leases, at various times during 1917, 1918, and 1919. Thus the future of the district is assured by the new "zoning" plan, although tenants of a different class must be found for the buildings already erected which will be vacated. Mr. Boucher.

Referring again to the comment that it is cheap, convenient, and frequent transit which apparently forms the basis of land values in the first instance, there are many persons who well remember when the districts lying north of 59th Street, Manhattan, were sparsely settled, where rocky hillsides and trees abounded, and where goats roamed at will in and around the shanties of the "squatters" who were the first settlers. At that time the means of transit were confined to horse cars and omnibuses, and as the time required to travel from the business sections at or around the City Hall to the neighborhood of 59th Street was fully one hour, it was about all that the patience or the physical health of the passengers could endure, as the cars were not heated and the feet found cold comfort in the straw loosely placed on the floors in winter. The elevated railway system was opened for traffic before 1880, and by 1884 had reached Harlem, and with its advent came the buildings and the people to fill them. A later instance, within the memory of all, is the Washington Heights Section of Manhattan and the sections of the Bronx made readily accessible by the subway opened in 1904. Until that date, only surface cars reached those districts, but, during the first 5 years after the trains began running, entire neighborhoods were transformed from open vistas and low valuations to closely built blocks of buildings with much enhanced values.

Again, this matter of the influence of transit facilities is very noticeable in Chicago. The four elevated railroad main lines are the

Mr. Boucher.

Northwestern serving the "North Side" and northwest section, the Oak Park (Lake Street) and Metropolitan serving different sections of the "West Side" and the South Side line serving the southern and southwest sections. Each has a very heavy morning and evening rush-hour traffic. The four lines reach the business section, as shown on the map, Fig. 7, and there jointly use the "Union Loop" on Wabash Avenue, Lake Street, Fifth Avenue, and Van Buren Street. The "Loop" was opened for traffic in 1897 and, until recently, all trains entering it passed entirely around it and left it at the point of entrance. It was merely a joint terminal, and fares began and terminated there; if a passenger desired to continue his ride, he left one train, went into and through a station, paying another fare and boarded the train of another company also stopping at that station platform. During the past 3 years, however, "through routing" has gone into effect, by which trains are run through from the North to the South Side and *vice versa*, and free transfers are issued from both these lines to the "West Side" lines.

The "Loop" has been termed both a blessing and a curse. In the first instance it provided a splendid terminal arrangement for all trains, from whatever section, giving preference to none and permitting passengers the maximum of convenience in the matter of reaching the down-town section, but, on the other hand, it has undeniably had the effect of creating the most congested business section in the United States. From Wabash to Fifth Avenues is about 2 000 ft., and between Lake Street and Van Buren Street is approximately 3 100 ft., and within this area of less than ½ sq. mile is concentrated the business center of America's second city. Towering buildings rise on every street, each street is almost equally thronged, although State Street, with its department stores, is noticeably the busiest. Pedestrian, car, and vehicle traffic combine to produce the very limit of impeded traffic. By a reliable count, made by unprejudiced observers in 1910, the number of pedestrians on State Street, passing the corner of Madison Street, was so great that, without doubt, it might be termed the most densely traversed locality in the world. Any fair Saturday afternoon, the 20-ft. sidewalk is thronged with densely-packed, slowly-moving crowds, which fill it from curb to building line, about equally divided between those moving north and those moving south, on both sides of the street.

In this section are the large retail stores, many wholesale stores, some warehouses, the banks, exchanges, hotels, theaters, office buildings, some light manufacturing establishments, in fact, everything that tends to draw people; the result has been that every foot of ground has been utilized by the erection of business buildings, mainly of a very good type, with the corresponding result that valuations and rentals are high.

Step beyond the limits of that "Loop", and on all sides (the East Side excepted) one immediately notices the difference. The buildings are of a different character, and the hurrying crowds are absent. Mr. Boucher.

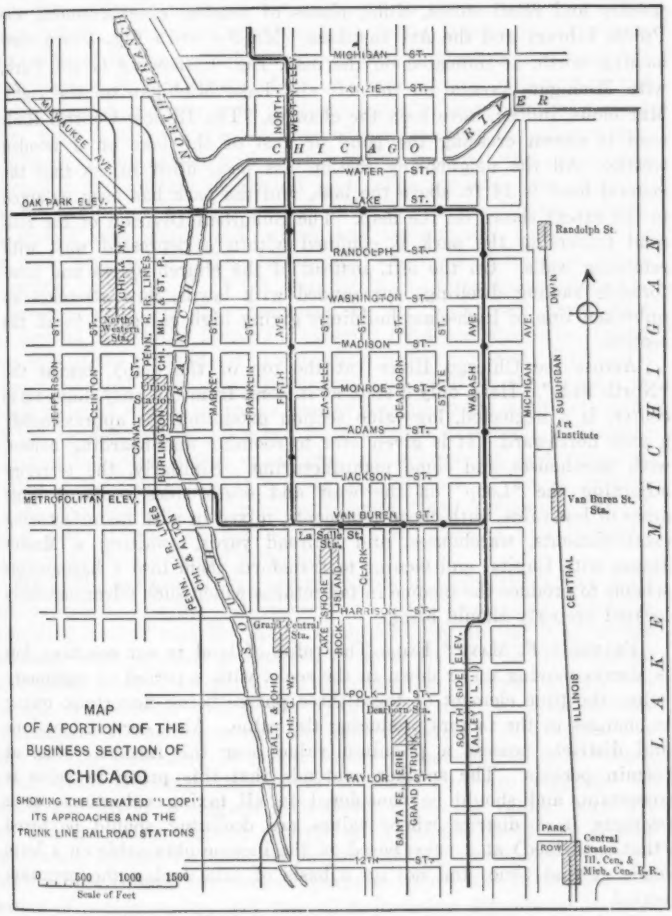


FIG. 7.

East of the Loop on Wabash Avenue, the city extends one block to Michigan Avenue, overlooking Grant Park and the Lake. Michigan Avenue, like Fifth Avenue, New York City, has been kept free of

Mr. Boucher. street cars, its traffic resembles that of the eastern city, except that it has no 'buses, and its development has been very similar. The buildings are of the highest class, consisting of office buildings, first-class jewelry and retail stores, clubs, places of musical entertainment, the Public Library and the Art Institute. Mr. Jerrard's Fig. 1 is a view looking north, as indicated on the map, Fig. 7, showing Grant Park, with Michigan Avenue on the left and Lake Michigan on the right. Marvelous, indeed, have been the changes. The Illinois Central Railroad is shown crossing the pond or arm of the lake on a wooden trestle. All the neighboring section has been filled in, so that the general level is 14 ft. above the lake, and the park has been enlarged to the extent shown on the map. The Suburban Division of the railroad traversing the park is confined within a depressed way, with retaining walls. On the left, instead of the church spires and comfortable looking dwellings surrounded with lawns, now stretches an unbroken line of high-class buildings giving high valuation to all the section.

Across the Chicago River (at the top of the map), begins the "North Side". Here, only a step, as it were, from the busy, high-value center, is a neglected, low-value section extending for approximately a mile northward. It is given over to rooming and boarding houses, with warehouses and some manufacturing. Similarly, the territory adjoining the "Loop" on the west and south sides contains large areas of low value, with cheap tenements, mixed in with manufacturing establishments, warehouses, and railroad yards, awaiting a Master Hand, with Capital and Genius to transform them into a harmonious scheme to produce the income in tax returns which such advantageously located property should bring.

Mr. Mayo. FRANKLIN F. MAYO,* ESQ.—The value of land is not constant, but is always moving up or down in the scale, with a period of stationary value, the time element of these three phases being uncertain, owing to changes in the factors producing the value. Also, certain locations and districts possess a premium value over the income value, at certain periods. The speaker contends that this premium value is uncertain, and should be considered in all taxing valuations, as a property in a district where values are declining should be taxed (that is, valued) at a price based on the income obtainable on a lease made at that time, and not on a basis of sale during the premium period.

To do this would require a keen sense of the human element factor, and no method of valuation would be satisfactory unless made by men especially qualified in placing values.

---

* Newark, N. J.

Mr. Jerrard.

L. P. JERRARD,* JUN. AM. SOC. C. E. (by letter).—The discussion of this paper has brought out several points which may be cleared up by further explanation. The writer's loose application of economic terms has evidently obscured his argument in several instances. Mr. King and Mr. Kelly both take exception to the statement: "The true value of land is the ground rent capitalized." Inasmuch as land has value because it is a source of ground rent, it would seem that the market value should bear some definite relation to the amount of ground rent. Such is not the case, in view of the fact that the ground rent is subject to fluctuation, and market values discount the prospective changes in the amount of ground rent. The intention was to bring out the distinction between market value and a value based entirely on ground rent capitalized, which was inaccurately designated by the term "true value". The statement, "The basis of business values is strictly economic, * * * but the basis of residence values has a social element," is also challenged by Mr. King, who states that the demand of wealthy people for pleasant residence sites is as strictly economic as the demands of any business utility for land. The social element referred to by the writer manifests itself in the demand of people of lesser wealth to live as near as possible to the wealthiest class. Of two residence sites, all other factors (such as schools and transportation facilities) being equal, the one nearest the best residence section of the community is ordinarily preferred. It would seem as though this tendency is more sentimental than economic, but, in either case, it was the distinction between business and residence values which was intended to be made.

Mr. Kelly has brought up several points to which the writer must take exception. To the deductions to be made from gross rentals in computing ground rent Mr. Kelly would add, "A sinking fund charge sufficient, when put out at interest, to cover the cost of the building in a given number of years." This charge is covered by the item "annual depreciation" which was included in the list of deductions. "Advantages of location govern the values entirely." By "values", as used in this statement, is meant values in general, or unit values, which would eliminate the factors of shape and size suggested by Mr. Kelly. He also suggests as a factor governing values, "utility", but does not utility depend entirely on location? Land has greater value when utilized for business purposes than for residence property; but it cannot be used for business purposes unless it is in the business section of a community, and even then its value depends on its particular location within the business section.

Mr. Kelly understands the writer to say that the greatest number of people pass through the heart of the city. Possibly he has in mind

* Chicago, Ill.

Mr. Jerrard.

the statement, "retail stores gather at the heart of the city" where the largest number of prospective customers will pass. It is frequently true, as Mr. Kelly states, that the greatest number of people pass some railroad terminal or ferry landing, but they are hurrying to and from their work and are not "prospective customers." It may be interesting to note that such corporations as the United Cigar Stores Company, and F. W. Woolworth Company, before locating one of their stores, make a careful investigation, not only of the number of people passing a prospective location, but of their wants, buying power, and inclination to buy at that point. It is possible that a cigar store would flourish at a terminal where no one would find time to patronize a five and ten-cent store. A traffic count might show a great number of people passing a certain corner, but, if they were mostly factory girls and women, it would not augur well for a cigar business.

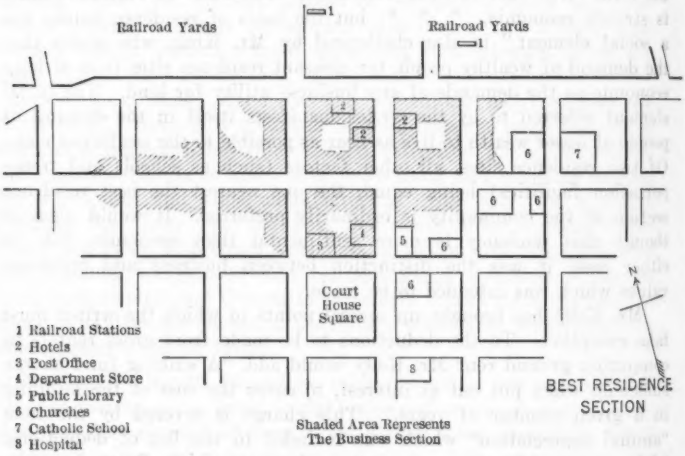

FIG. 8.

"The retail section moves in the direction of the best residence section." It is true, as Mr. Kelly suggests, that local conditions sometimes alter or retard this tendency, but the tendency persists nevertheless. The writer noted an interesting situation recently in Watertown, S. Dak. The sketch, Fig. 8, is from memory only and not accurate, but illustrates the situation approximately. The business section is separated from the best residence section by a zone of public buildings, churches, and other permanent institutions, which must form a substantial barrier to the extension of the business section in that direction. To the west and north, where there is room for the expansion

of the business section, there is nothing more attractive to business than railroad yards and river bottoms. The tendency of retail business to reach out toward the best residence section seems to be illustrated by the location of a large department store, the best in the city, on the edge of the business section, but on this side most convenient to the best residence district. Mr. Jerrard.

Mr. Walker speaks of the Somers system of assessing cities, with the aid of community opinion. In fixing the point of greatest value at 100%, and determining the value of all surrounding frontage in percentages thereof, as explained by him, it would seem that all errors which may be introduced are cumulative. If an incorrect relative value is established for any block, the error is reflected in a series of blocks the values of which are relative to the one in error. The writer has seen evidence of the partial failure of the Somers system in this respect, and has also noted that, in the public meetings and discussions, the principal efforts are made by those land owners who are most directly interested, and that the conclusions are likely to be biased in their favor.

Mr. Rankin has introduced some interesting and pertinent data with regard to the value of the best business land in cities. With respect to the discrepancy between the points plotted by Mr. Rankin and the curves advanced by the writer (Fig. 2), the following influences are suggested as regards Mr. Rankin's data:

1.—Population of cities does not include tributary suburbs (mentioned by Mr. Rankin);
2.—Undue optimism which frequently prevails among real estate dealers regarding land values;
3.—Difficulty of determining, in the business districts of a city, values which are free from corner influences.

All these factors would tend to throw the points plotted by Mr. Rankin away from the curves. Part of the data on which these curves were based, are here submitted, and also shown in Fig. 9. Mr. Alfred D. Bernard, in "Some Principles and Problems of Real Estate Valuation", states as follows:

"In a normal city for populations above 50 000 the value of the best retail business property is one cent per front foot per person.

"City.	Population.	Best Land per Front Foot.
Boston	1 500 000	$15 000.00
Philadelphia	1 500 000	15 000.00
Baltimore	650 000	6 000.00

"Baltimore has a large negro and low wage earning population and values are below normal. Cleveland, Louisville and Minneapolis will prove the rule."

Mr. Jerrard.

Mr. Richard M. Hurd* has given the figures reproduced in Table 9. From miscellaneous sources, including some of the writer's own determinations, city assessments by the Somers method, and opinions of real estate dealers, the data in Table 10 have been collected.

TABLE 9.

City.	Population.	Best business per front foot.
Washington	270 000	$5 000
Louisville	205 000	1 700
Minneapolis	203 000	2 500

Madison, Wis	30 000	2 000

In Mr. Thomson's opinion, this paper suggests in too strong a manner that the engineer is a better authority on real estate than the real estate man. There is no implication that the engineer has

* In "Principles of City Land Values."

Mr. Jerrard.

any place in the general field of the real estate business, which includes platting, buying, selling, renting, and managing property, and the question pertains only to making land valuations. In valuation, it is felt that some of the work of real estate men is inaccurate, and that, in many cases, some effort should be made to check the appraisals submitted by them. This is especially the case in smaller cities. As an indication that many valuations made by real estate men are in error, the writer may cite the frequent instances of wide variations in the valuation of the same property by different appraisers. The writer has had some experience, in cities of less than 50 000 population, in obtaining two valuations of the same property from the same man at intervals of several weeks or months. It is not uncommon to find

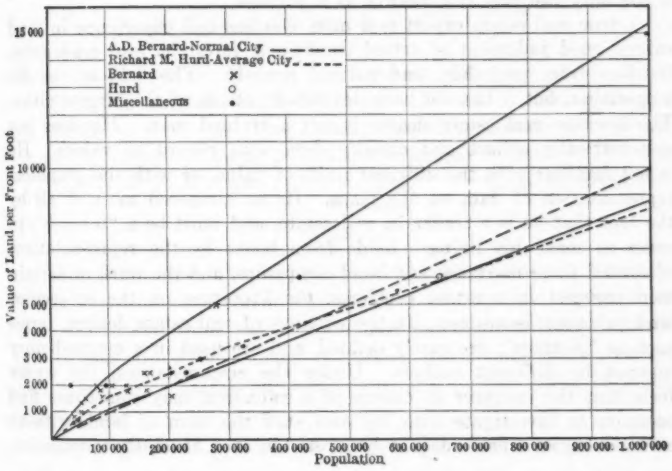

FIG. 9.

considerable variation in the results in such cases. If a deliberate attempt is made to confuse the real estate man by argument, or by introducing units of value with which he is unfamiliar, a very wide variation in results may be obtained under the same circumstances. In all these cases, an effort was made to obtain the services of the best informed man in the community.

Some organizations, which require land valuations to be made in different cities, proceed in the following manner: A complete record of real estate sales is obtained from abstractors and from public records. The services of a local real estate man are obtained, and he states what unit of value is most familiar to him, such as the lot, square foot, or front foot. The sales data are then reduced to the same unit and

Mr. Jerrard.

plotted on a map, together with information collected as to the extent of improvements on properties sold, assessment records, etc. The map is then turned over to the expert, who studies the situation and makes the valuation of the land in question. Satisfactory results are obtained in this manner. The experience of such organizations has been that, if the data are not provided for the expert, he will not obtain all of them, nor will he reduce them to the form in which they are most applicable to the problem. If the information is expressed in units with which he is unfamiliar, he cannot readily understand it or convert it to another unit. It is not unlikely, in cases such as these, that the man who collects and prepares the data becomes as familiar with the values involved as the local expert, but, in a contest, the local expert is the only one who can qualify as a witness.

A true real estate expert is a man who has had experience in land values, good judgment of actual conditions, foresight into tendencies, freedom from prejudice, and natural honesty. The field is one for a specialist, but it has not been developed outside of the largest cities. The average real estate dealer is not a trained man. He does not systematically collect and classify data with regard to values. He is not familiar with the different units of value, or with the graphical representation of data on the maps. He is hampered most of all by the fact that he is a trader in real estate, and must be a "booster", in order to make his living. Aside from books by the representatives of several large mortgage and bond companies, and the work of certain men engaged in taxation problems, the literature on the subject of land valuation is meager. In the writings of real estate dealers, terms such as "plottage", are rarely defined, and are used in a contradictory manner by different authors. Under the circumstances, the writer feels that the engineer in charge of a valuation may sometimes find occasion to investigate with his own staff the item of land, without encroaching on a field adequately covered by men of another profession.

Paper No. 1393

TESTS OF CONCRETE SPECIMENS IN SEA WATER, AT BOSTON NAVY YARD*

By R. E. Bakenhus, M. Am. Soc. C. E.

With Discussion by Messrs. T. Kennard Thomson, J. J. Yates, J. R. McClintock, S. B. Williamson, Waldo C. Briggs, Charles S. Bilyeu, W. E. Day, Robert Ridgway, George W. Fuller, A. H. Rhett, Marshall W. Brown, Albert Larsen, W. Watters Pagon, R. J. Wig and Lewis R. Ferguson, and R. E. Bakenhus.

Synopsis.

This paper describes a test of twenty-four concrete specimens which were immersed in sea water for 7 years. The object of the tests was to determine the action of sea water on concrete specimens of wet and dry consistencies, of various proportions of ingredients, and of different brands of cement, as well as the effect of special compositions.

The methods of mixing, analyses of the various cements, sand, and stone, and the conditions of the test, as well as all other data having possible effect on the results, are stated in the paper. The information is given in tabular form where possible.

The specimens were examined at intervals of about one year, and record was made of their condition. The results of these observations have been tabulated, and show progressive deterioration of some of the specimens and remarkable durability of others. Recently, the specimens were examined with great care, and graded in the order of durability. These results are also tabulated. Independent tabulations are made of the various series of tests originally planned, to

* Presented at the meeting of January 3d, 1917.

ascertain in one case the effect of wet and dry mixture, in another case the effect of rich and lean mixture, and in others the effects of special brands of cement, and of using lime, Sylvester wash, etc., with the cement.

The results are interesting, and seem to show, briefly:

(*a*) That the 1:1:2 mixture is superior to the 1:2½:4½, and that the 1:2½:4½ is, in turn, superior to the 1:3:6;

(*b*) That the wet mixtures are superior to the dry;

(*c*) That the effects of magnesia or alumina in varying proportions are not very marked, and follow no apparent law, although the two most durable specimens are those lowest in alumina content;

(*d*) That extra care in mixing produced decidedly beneficial results;

(*e*) That hydrated lime was of no benefit, but rather a detriment;

(*f*) That the addition of Sylvester wash was harmful; and

(*g*) That the addition of clay to the cement had a slightly beneficial result.

The deterioration occurred between high and low water, and was most marked at mid-tide. Above high water there was little deterioration, and the same is true, but to a less marked extent, of the concrete continually submerged.

A careful reading of the paper should be made before any of the foregoing conclusions are applied. The experiments are not sufficiently extensive to warrant drawing final conclusions in all cases, unless confirmatory evidence is available. In utilizing the results, the limitations of the tests and local conditions should be taken into account.

About 7 years have elapsed since twenty-four concrete specimens were placed in sea water at the Boston Navy Yard. The results, on careful analysis, give information of considerable value. This paper presents a résumé of the important facts in regard to the preparation of the specimens, the recorded observations at stated periods, and a tabulation and discussion of the results to date.

The various facts and observations connected with the tests are given in full, so that those who wish may study them and draw their

own conclusions. Those who are sufficiently interested may observe the specimens at the Navy Yard. In the latter part of this paper the principal results of the tests are summarized, and the conclusions of the writer are stated, without attempted explanation, however, as to the causes of the different kinds of action on the concrete specimens.

The expense of making the tests is borne entirely by the Aberthaw Construction Company, of Boston, who proposed them and entered into agreement with the Navy Department, represented by the late Fred Thompson, M. Am. Soc. C. E., Civil Engineer, U. S. Navy. The agreement (Appendix A) covers the conditions of the tests whereby the specimens were permitted to be made and exposed in the Navy Yard, all work being under the inspection of the Civil Engineer, now Public Works Officer, of the Yard, and the Navy Department having the right to observe the specimens and to use the information obtained.

Each of the twenty-four specimens is 16 ft. long and 16 in. square, weighing from 4 050 to 4 350 lb. They are hung on Pier 9, at the Boston Navy Yard, in such a manner that the lower ends are continually immersed, the upper ends but rarely immersed, and the center portions are subject to alternate action of the air and salt water due to the 10-ft. tides.

The specimens were originally suspended, in February, 1909, from the old Pier 9, but, as this was rebuilt, they were moved on December 5th, 1911, to Pier 8, east side. Later, it became necessary to renew the supporting bridles, and, on September 19th and 20th, 1912, the specimens were removed and leaned against the quay wall and on October 30th and 31st, 1912, were moved to the newly constructed Pier 9. The piers are of open wooden pile construction, giving the sea water a free flow. About April, 1914, a pipe line for furnishing fuel oil to naval vessels was placed on Pier 9, and since then the concrete has become coated with a thin film of fuel oil. The sea water is that of Boston Harbor, analyses of which will be given. Fig. 1 is reproduced from a photograph showing the specimens as suspended from Pier 9 in April, 1916.

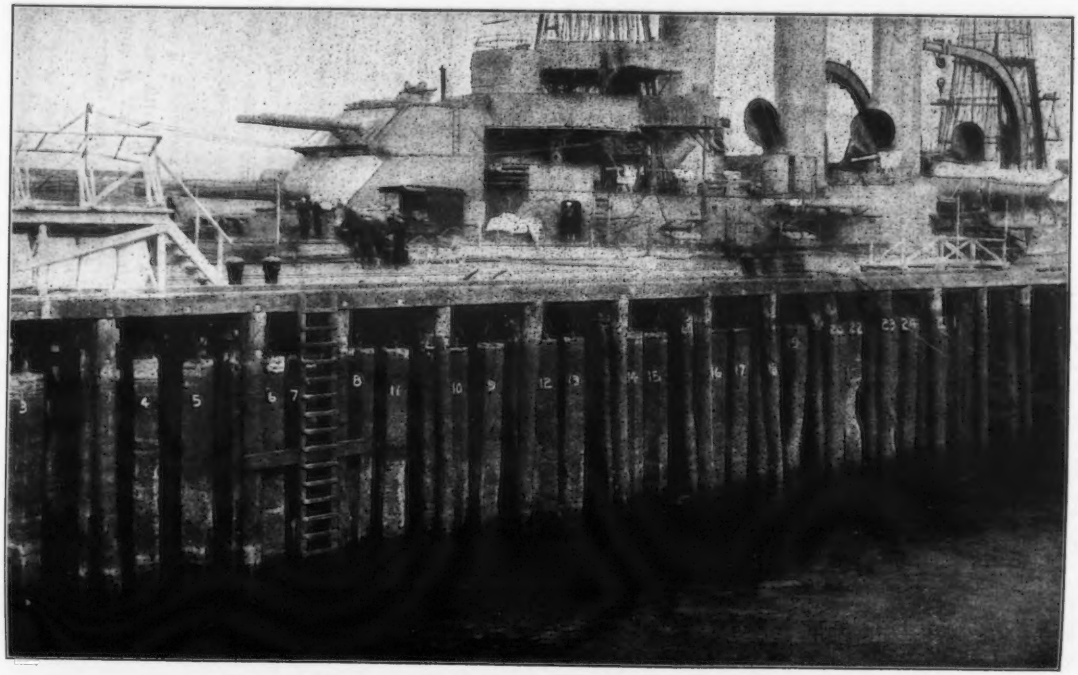
The specimens were lifted out of the water on December 9th and 10th, 1913, for the purpose of photographing them, and were immediately replaced.

The following description of the manufacture of the specimens is taken from the file copy of the records made at the time:

"The specimens were made on the first floor of Building No. 107 at the Navy Yard, which was kept above freezing point but yet not very warm. The feeding chute was removed, and materials were shoveled directly from the floor to the mouth of the mixer, which was about 3 ft. above. The materials were dumped into a water-tight mortar box, from which they were shoveled into wheel-barrows and wheeled to forms made of plank a short distance away. The specimens were cast in a horizontal position. Embedded in each for its full length and projecting from the end (forming a loop) was a $\frac{3}{8}$-in. square twisted steel bar, bent in its middle (embedded near diagonal corners), to give the specimens stiffness, so that they could be handled without breaking. There was also embedded in the upper end of each specimen for a depth of 8 ft. a steel pipe, $2\frac{1}{2}$ in. outside diameter. This was used merely to core a hole and, after the specimens were set, was removed in the following manner: Before placing, it was coated on the outside with paraffin. After the specimens were set, live steam was turned into the pipe, which then was removed easily and quickly. In the very top of each specimen was embedded a 3-in. pipe which was threaded and capped. The object in coring this hole and capping it was to see if sea water percolated into the center of specimens. (This was used afterward for fastening hooks supporting the specimens when the loops had rusted away.)

"The sand and stone were measured in accurately made frames. In measuring they rested on a perfectly smooth hardwood floor. The materials were struck smooth on top with a straight-edge. The frames were made deep in order to avoid the large errors in volume which occur when frames are very shallow and cover a large area. The sand and stone were completely fed into the mixer first; then cement was shoveled in, which took about 1 min. After $\frac{1}{2}$ min., water was added with pails, being accurately weighed. This took about 1 min. to add. In every case, in as near 2 min. as possible after the first water was added, the batch was dumped from the mixer. It took from 15 to 18 min. to place a batch entirely in the forms, into which it was thoroughly spaded and tamped. The workmanship was intended to reproduce as nearly as possible actual commercial conditions.

"The first nine specimens, which were made from a standard average composition Portland cement, were made by mixing together equal parts of Vulcanite, Alpha, and Giant. These were thoroughly mixed in the mortar box and then repacked by weight. The cement free from iron was Blanc Stainless; the commercial Portland high in alumina was Atlas; the commercial Portland cement low in alumina, was a mixture of equal parts of Lehigh and Helderberg; the iron ore cement practically free from alumina was Hermmoor Erz German Portland cement; and the Portland cement, made from blast-furnace slag and limestone, was Universal.



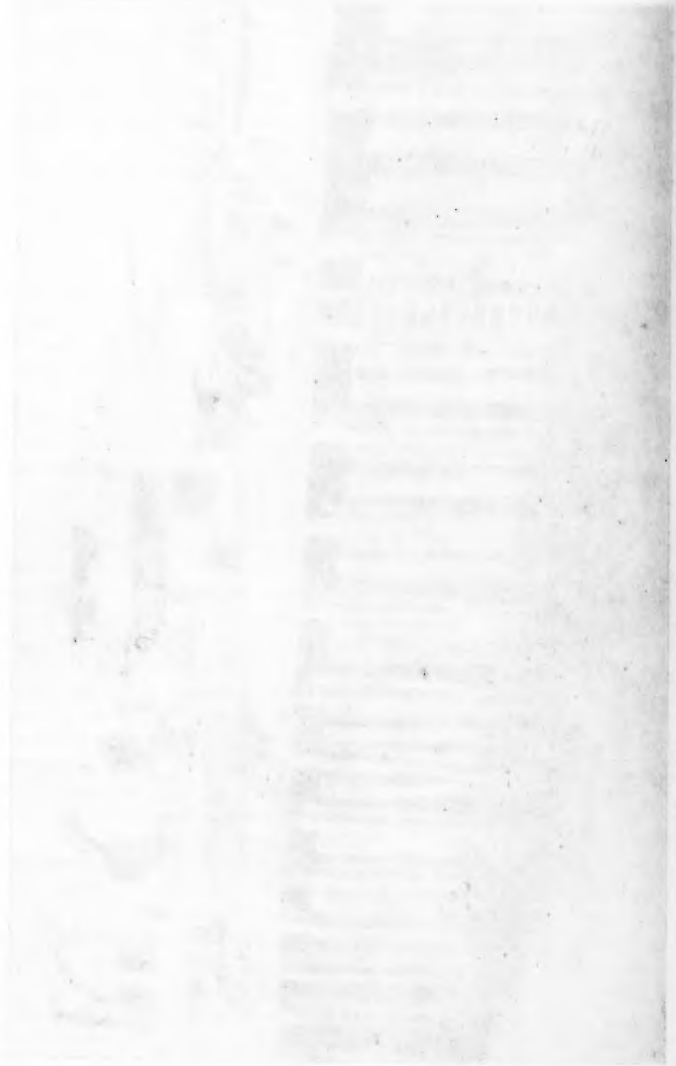


FIG. 1.—CONCRETE SPECIMENS SUSPENDED FROM PIER 9, BOSTON NAVY YARD.

"The stone was broken trap rock from the quarries of E. Burnett, Franklin Park ledge, Malden, Mass. A cubic foot of stone weighed 90.24 lb. Determination of voids in stone was 50 per cent. The stone passed a 1¼-in. ring, with the dust screened out.

"The sand was clean and sharp, a little finer than usual, from the bank of P. O'Riorden, at South Acton, Mass. Dry, it weighed 97.18 lb. per cu. ft. Determination of voids in the dry sand was 34.2 per cent. As used in the work, the sand contained 4.6% of moisture by weight.

"With the above determined percentage of voids, the mixture, nominally 1:2:4 but proportioned so as to have 10% excess of cement over the voids in sand, and 10% of mortar over voids in the stone, was actually proportioned 1:2¼:4½.

"The specimens remained in the building for about 5 weeks. They were then loaded on flat cars and moved to Pier 9 in the Yard, and were hung from the cap log, as shown by Fig. 1. During the loading of the specimens, they were calipered in each direction close to each end and every 2 ft. along their length. Their length was also measured and the length to which the core pipe was embedded. Before hanging from the pier, they were weighed on platform scales.

"In the process of moving and setting, Specimen No. 22 was cracked clear through, at about 6 ft. from the lower end, and Specimen No. 23 had a very small crack on the face, about the middle.

"From concrete left over from filling the forms, fifteen 8-in. cubes were made of mix similar to Specimen No. 3, and fifteen others were mixed similar to Specimen No. 9. These were put in a box for convenience in keeping them together; one-third were immersed permanently; one-third were supported at half-tide; and one-third were kept in a dry place exposed to the weather."

The analyses of sand and stone made by Mr. Herbert L. Sherman for the Aberthaw Construction Company, as given in Table 1, apply to all the specimens.

TABLE 1.—Analyses of Sand and Stone Used in all Specimens.

Bank Sand.

Magnesium chloride.....	2 132.1	124.3
Sodium chloride.....22 980.4		1 339.8
Potassium chloride.....	956.4	55.9

Table 3 shows the scheme of the tests. For the purpose of this report, they have been arranged in eleven series, according to the cement used. Those in series II to XI, inclusive, in every case have parallel tests in Series I, which is the principal one.

Table 3-*A* gives, for each specimen:

(*a*) The important dates;

(*b*) The materials of which made;

(*c*) The proportions.

The percentage of water used, as given in the tables, is not an absolute guide to the quantity in the concrete, because, during a portion of the tests, a snow storm caused the sand and stone to become wetter initially.

The progressive condition of the specimens is shown in Table 4 where the information is collated for convenient reference.

The observations as to condition of the specimens were made at various times by Mr. E. S. Phelps, DeWitt C. Webb, M. Am. Soc. C. E., Civil Engineer, U. S. Navy, and by the writer.

Note.—The weight of water, in pounds per cubic foot, takes

A very careful examination, by three experienced observers, was made in April, 1914, at low tide, of all the specimens, and they were graded and classified on the spot in accordance with their condition at the time. The estimates of grade and class were on the basis of durability or serviceability of the concrete, as if it were in actual service. The examination was made after the specimens had been in the water 5 years, since which time there have been no changes of note. The various classes, especially the upper ones, grade into one another with definite, but without particularly strong, dividing lines. The specimens in each class are arranged from left to right in the order of durability.

The following is a copy of the report on classifying and grading the specimens:

"April 1st, 1914.

"Specimens graded largely as to condition at point of maximum deterioration.

"Specimens in order of durability.

"Elevation of tide, 1 ft. above mean low water at time of examination.

SCHEME OF TESTS.

Series VI. Universal Cement Al_2O_3 8.04% MgO 1.63%		Series VII, like Series I. Concrete extra well mixed. Al_2O_3 7.21% MgO 2.74%		Series VIII, like Series I, using sea water.		Series IX, like Series I, with lime.		Series X, like Series I, with Sylvester Solution.		Series XI, like Series I, with 5% Clay.

TO MIXTURE OF CONCRETE.

WEIGHTS (ALL IN POUNDS): Of water in batches.	Total of water.	Total of cement.	Of specimen.	Per cubic foot.	Of water per cubic foot.	Volume of concrete, in cubic feet.	Percentage of water to total weight.	Percentage of water to cement, by weight.	Condition of concrete after mixing.
88 80 80	248	1128	4057.5	152.1	9.3	26.68	6.1	22	Water glistened, but did not spatter or quake.
107 93 95	295	1128	4267.5	151.06	10.4	28.25	6.9	25.2	No water spotted surface from tamping, but a little movement could be seen 12 in. from tamp.
125 150 150	425	1128	4197.5	145.04	12.5	28.044	8.4	37.6	Soft enough to run out of overturned wheel-barrow, but would not flow like syrup. First two batches required a little tamping. Third batch showed quake when tamping.
58 55 52	165	1128	4122.5	145.82	5.9	28.267	4.0	14.6	No free water, but surface was moist. Shoveled from barrow and every shovelful tamped by two men.
66 63 66	195	1128	4127.5	150.3	7.1	27.46	4.7	17.2	Top surface quite wet. Just barely spattered, and quaked a very little at a few inches from tamp.
125 115 105	345	1128	4297.5	152.2	12.2	28.225	8.0	31.4	Nothing in report.
47 45 45 45	182	1504	4097.5	142.5	5.8	28.74	4.1	12.1	When filled glistened at a point about 4 ft. from end. Did not quake.
60 60 60	240	1504	4202.5	146.58	7.7	28.67	5.7	16	Moderate tamping showed quaking; spots of water on surface.
88 85 85	343	1504	4162.5	145.4	11.3	28.62	7.8	22.8	Forms filled and water ran off, spattered and quaked.
95 100 110	305	1128	4267.5	142.1	10.2	30.03	7.1	26.2	Quaked when tamped lightly. Quite wet when dumped. Cement acted quickly.
100 100 93 60	353	1455	4297.5	146.20	12.1	29.39	8.5	24.2	Flowed off shovel easily. Showed quaking, and spattered from light tamping. Concrete when tamped flowed water off form. This concrete set before that of No. 10 specimen made previously.
105 110 110	325	1128	4172.5	145.9	11.0	28.58	7.5	28.8	Quaked with light tamping. Spotted on surface.
95 95 95 60	345	1504	4047.5	142.8	11.3	28.34	7.9	25.1	Flowed off shovel easily. Tamping showed quaking. Spattered when tamped hard. Surface glazed. Light tamping showed quakes.
110 110 110	330	1128	4077.50	144.2	10.7	28.27	8.1	29.1	Quakes with light tamping. Spattered and showed water on surface.
95 95 95 50	335	1504	4072.50	142.7	11.7	28.52	8.2	22.1	Showed quaking, light tamping. Surface glistens.
105 105 105	315	1134	4237.5	149.6	11.1	28.32	7.4	29.2	When leveled off showed oily streaks in water on top. Very dark, more like black mud mixture. Very oily surface. Showed quake in light tamping. Very soft after 24 hours' set; finger nail made impression.

TABLE 3-A.—

No. of specimen.	Kind of mixture.	Dates: (All in 1909.) Of mixing.	Forms removed.	Immersed.	Kinds of cement used.	Proportions.	No. of batches.

deterioration between 1914 and 1916. It is to be noted that all those that have deteriorated are in the lowest classes as to durability. Careful consideration showed that the classification made in 1914 need not be changed.

All specimens since 1914 have become coated with a fine layer of crude fuel oil between extreme high and low waters. This coating hides many of the minor defects in the specimens. The oil comes from the outlets placed on Pier 9 for fueling naval vessels.

The report of April, 1914, on the durability of the concrete, forms the basis for all the analyses of the results and for all the conclusions drawn. A tabulation and a discussion of results is offered in the following pages. Reference is made particularly to Table 3, showing the scheme of the tests and the division of the tests into thirteen series, each devised to show the effect of some particular condition, material,

(Continued).

Weights (All in Pounds): Of water in batches.	Total of water.	Total of cement.	Of specimen.	Per cubic foot.	Of water per cubic foot.	Volume of concrete in cubic feet.	Percentage of water to total weight.	Percentage of water to cement, by weight.	Condition of concrete after mixing.
80 80 80 53	293	1417	4172.5	145.9	10.2	28.59	7.0	20.8	Water showed on oily surface. Quaked on tamping. After 3 days showed a crust on surface.
110 110 110	330	1128	4162.5	145.6	11.5	28.58	7.9	29.2	Quaked with light tamping. Very dark in color.
100 100 100 70	370	1410	4072.5	143.3	13.3	28.43	8.6	25.6	Quaked from light tamping. Showed water on surface, not enough to spatter from tamping.
75 75 75 50	275	1410	4112.5	145.5	9.7	28.26	6.7	19.5	Showed quaking and spattered when spading sides. Water flowed over surface and down sides of forms.
75 75 75 50	275	1410	4147.5	147.0	9.7	28.21	6.6	19.5	Showed quake; water flowed over surface.
90 95 90 50	325	1410	4172.5	146.7	10.7	28.43	7.3	22.7	Showed quake on light tamping; also spattered. Specimen cracked in center.
80 85 53	298	1410	3997.5	137.9	9.6	28.97	7.0	21.2	Quaked and spattered when tamping. Very fine cracks near middle.
75 75 75 50	275	1410	4097.5	151.6	9.5	26.97	6.2	19.5	Showed quaking, and spattered from light tamping.

or process. The scheme of tests is as planned by those who originally laid them out; the table is devised for the purpose of this paper.

The following important results are shown by an examination of Table 5:

(*a*) The effect of proportions of materials is the most marked phenomenon developed in the tests.

(*b*) In every instance the specimen richer in cement is more durable than the corresponding leaner specimen, which is shown in detail by referring to Table 3 in connection with Table 5, as follows:

No. 1 is better than No. 4, which in turn is better than No. 7.
" 2 " " " " 5 " " " " " " " 8.
" 3 " " " " 6 " " " " " " " 9.
" 10 " " " " 11

14	No action.	No action.	No action.	No action.	No action.	No action.	No action.
15	Fair; slight action on front.	No action, except slightly rough on face.	Back slightly flaked.	Slight deterioration, face and side.	Faces slightly marked.	Concrete slightly soft in spots. Face and sides pitted; slight erosion.	Concrete soft in spots. Face and sides pitted; slight erosion.
16	No action.	No action.	No action.	No action.	No action.	Very slight pitting at extreme low water.	Very slight pitting at extreme low water.
17	No action.	No action.	All sides flaked.	All sides flaked.	All sides very slightly flaked.	All sides pitted. Front badly pitted at M. L. W.	All sides pitted. Front badly pitted at M. L. W.
18	No action.	No action.	No action.	No action.	No action.	Sides perfect. Front and back slight pitting.	Sides perfect. Front and back pitted.
19	Very good. Face slightly rough.	No action, except slightly rough on face; cracked.	Face eroded. Concrete soft.	Back disintegrated; concrete very soft.	Badly flaked; concrete crumbling back 4-in. hole.	Face badly pitted; concrete soft; back eroded 4 in. deep.	Concrete soft and spongy; face pitted; sides badly eroded.
20	Very good. Face slightly rough.	No action, except slightly rough on face; cracked.	No action, except back flaked.	Slight deterioration at M. L. W.	Flaking all sides; corners worn.	Concrete fairly hard. Face eroded. Sides and back somewhat pitted.	Concrete fairly hard. Face eroded. Sides and back somewhat pitted.
21	Very good. Face slightly rough.	No action, except slightly rough on face; cracked.	Sunken.	Lost.	Lost.	Lost.	Lost.
22	Good; crack on face.	Rough on face.	Face and back eroded.	Face and sides eroded; edges broken.	Badly marked; 4-in. hole on face; concrete soft and dead.	Face eroded 6 in. over space 3 ft. Sides and back pitted. Concrete soft.	Face eroded 7 in., length 4 ft. Sides and back eroded from 1 to 3 ft. Concrete soft.
23	Cracked. Corners broken.	Cracked. Corners broken.	Face and back edges eroded.	Edges badly broken away.	Face badly flaked; edges bad.	Concrete eroded from 4 to 8 in. at M. L. W. Soft.	Concrete eroded from 5 to 8 in. deep about M. L. W. Concrete soft below M. L. W.
24	Good. Face slightly soft.	No action.	No action, except edges eroded.	Back edges worn; mortar on face deteriorated.	Face slightly marked. Edges worn.	Faces and sides pitted. Edges slightly soft on lower half Spec. Concrete fairly hard.	Faces and sides pitted. Edges slightly soft on lower half. Concrete hard.

TABLE 4.—PROGRESSIVE CONDITION OF SPECIMENS.

February, 1909.	March, 1910.	March, 1911.	June, 1912.	November, 1912.	December, 1913.	April, 1914.	January, 1916.
1	Face rough.	Face rough, 1 in. deep.	Face rough, 1 in. deep.	Face eroded, 1 in. deep.	Face badly eroded.	Face badly eroded; porous spots.	Face badly eroded; some porous spots.
2	No action.	No action.	No action.	Slightly rough face; slightly porous.	Faces slightly pock-marked.	Edges slightly soft; faces practically perfect.	Edges slightly soft; faces practically perfect.
3	No action.	No action.	Sunken.	Slightly rough face; scale on back.	Face and back slightly pock-marked.	All faces very good; surface slightly pitted; slight injury to edges.	Faces very good; surface slightly pitted. Slight injury to edges.
4	Face pitted 1 in., sides less.	Face pitted 1 in., sides less.	Sunken.	Very rough face; concrete porous.	Face badly eaten; back flaked; sides rough.	Face badly eroded; little pitting and erosion.	Face badly eroded; some pitting and erosion.
5	No action.	No action.	No action.	Face slightly rough; porous spots on back.	Faces (all) pock-marked.	Some erosion on face; pitting on one side.	Some erosion on face; pitting on one side.
6	Very good. Surface soft.	No action.	No action.	Edges slightly broken.	Fine condition. Corners worn; face marked.	Edges show action. Face pitted; soft spots on back.	Edges show action. Face pitted; soft spots on back.
7	Face pitted; sides less.	Face eroded; sides good.	Considerable erosion, front and back.	Badly eroded, back and face; corners soft and crumbling.	Very poor; concrete soft and crumbling.	Very poor condition; 2½ in. in length completely gone.	Very poor condition; 5 ft. in length completely gone.
8	No action.	No action except back eroded.	Back eroded 4 in; concrete soft.	Back disintegrated. Sides and face rough. Concrete soft.	Front and sides marked. Back 5-in. hole.	Face and sides slightly pitted. Back eroded 4 in. deep.	Face and sides slightly pitted. Back eroded 5 in. deep; rods exposed.
9	No action.	No action.	No action, except back chafed.	Edges worn. Slightly rough face.	Face marked. Edges worn.	Face badly pitted; sides and back slightly pitted.	Face badly pitted; side and back slightly pitted.
10	No action.	No action	No action.	Slightly rough face.	Face marked.	Some erosion on face; side and back slight pitting.	Some erosion on face; sides and back slight pitting.
11	No action.	No action.	No action.	Slightly rough face.	Face and sides marked.	Concrete hard, but chalky on surface. Edges soft. Face and sides very good.	Concrete chalky on surface. Edges soft. Face and sides good.
12	Very fair. Small areas on face have action noticeable.	No action, except slight roughness on face.	No action, except back slightly peeled.	Slightly rough face. Porous spots on back.	Back and face very slightly marked.	Very slight pitting on back; other faces fine.	Slight pitting on back; other faces fine.
13	Very slight action on face.	No action, except slight roughness on face.	No action, except slight erosion on back.	Slight disintegration of face.	Face marked; edge worn 2 in. deep.	Face pitted entire length; edges soft. Back slight pitting.	Face pitted entire length; edges soft Back slight pitting.

No. 12 is better than No. 13
" 14 " " " " 15
" 16 " " " " 17
" 18 " " " " 19

(*c*) Only specimens of 1:1:2 mixture appear in the first three classes.

(*d*) The specimens of 1:2½:4½ (the next richer) mixture appear in Class 4.

(*e*) The one specimen of 1:1:2 mixture, *viz.*, No. 1, and those specimens of 1:2½:4½ mixture which fall below the others of their class, evidently do so from being mixed dry.

(*f*) The poorest specimens were of 1:3:6 mixture.

TABLE 5.—CLASSIFICATION OF CONCRETE SPECIMENS, AFTER 5 YEARS OF EXPOSURE IN SEA WATER, IN THE ORDER OF DURABILITY, SHOWING THE INFLUENCE OF THE PROPORTIONS OF MATERIAL.

Analysis of Series I to VII, inclusive, Table 3.

1:1:2 mixtures marked ○
1:2½:4½ mixtures marked □
1:3:6 mixtures not marked.

Durability.	Specimen No.

Class II...	③	⑯			
Class III...	⑱	⑫	⑩	②	
Class IV...	[6]	[5]			
Class V...	15	20	24	17	①
Class VI...	9	11	13		
Class VII...	[4]	8			
Class VIII...	22	19	23		
Class IX...	7				

The important effects of the quantity of water used in mixing are as follows:

(*a*) The weight of water, in pounds per cubic foot of concrete, takes no account of moisture in the ingredients before mixing.

(*b*) Specimens 1, 2, and 3 were made in order to test the effect of varying proportions of water. The results show durability—least with the dry and greatest with the very wet.

(*c*) Specimens 4, 5, and 6, also made to test the effect of varying proportions of water, show least durability with the dry and greatest with the very wet, this being slightly better than the wet.

(*d*) Specimens 7, 8, and 9 were also made to test the effect of varying proportions of water, and again show least durability with the dry and greater with the very wet specimen.

(*e*) In general, the results show that dry mixtures are of the least value, and that wet or very wet mixtures decidedly improve the durability.

TABLE 6.—CLASSIFICATION OF CONCRETE SPECIMENS, AFTER 5 YEARS OF EXPOSURE IN SEA WATER, IN THE ORDER OF DURABILITY, SHOWING THE INFLUENCE OF THE QUANTITY OF WATER USED IN MIXING.

Analysis of Series I to XIII, inclusive, Table 3.

Specimens of a dry mixture marked D.

Specimens of a wet mixture marked W.

Specimens of a plastic mixture marked P., equals wet W.

Specimens of a very dry mixture marked V. D.

Specimens of a very wet mixture marked V. W.

Pounds of water per cubic foot of concrete shown below the number.

Durability.	Specimen No.

TABLE 7.—CLASSIFICATION OF CONCRETE SPECIMENS, AFTER 5 YEARS OF EXPOSURE IN SEA WATER, IN THE ORDER OF DURABILITY, SHOWING THE INFLUENCE OF THE QUANTITY OF WATER USED IN MIXING.

Analysis of Series I (Table 3).

Durability.	Very wet.	Wet.	Dry.
Class I.....			
Class II.....	(3)		
Class III.....		(2)	
Class IV.....	[6]	[5]	
Class V.....			(1)
Class VI.....	9		
Class VII.....		8	[4]
Class VIII.....			
Class IX.....			7

Table 7 shows more clearly than Table 6 the effect of varying quantities of water used in mixing, because only those specimens are included which were devised to test this particular feature. The results were as follows:

(*a*) The bad effect of a "dry" mixture is plainly shown. In each of the three series the dry specimen is the least durable and the very wet the most durable.

(*b*) The 1:1:2 mixture is the most durable of each of the three classes of specimens, the dry, the wet, and the very wet.

(*c*) The 1:2½:4½ mixture is more durable than the 1:3:6 in each of the three classes of specimens, the dry, the wet, and the very wet.

(*d*) Dryness of mixture has caused one of the specimens (No. 1), rich in cement, to be less durable than two (Nos. 5 and 6), with a lesser proportion of cement. Also, a dry specimen having a medium quantity of cement (No. 4) proved less durable than a wet specimen with less cement.

The following are the important results developed, as shown by Table 8:

(*a*) It happens that the two most durable specimens are those lowest in alumina content, and, above a percentage of 7 in alumina content, no relation to durability is apparent.

(*b*) The relation of magnesia content to durability is not established, although it is noted that the first three specimens have a lower total magnesia content than the last three; but this condition is not borne out in Series XIII, Table 9.

(*c*) It is a curious condition that in the two best specimens the relation between the alumina content and the magnesia content is 2.2, the lowest of any.

TABLE 8.—CLASSIFICATION OF CONCRETE SPECIMENS, AFTER 5 YEARS OF EXPOSURE IN SEA WATER, IN THE ORDER OF DURABILITY, SHOWING THE EFFECTS OF THE ALUMINA AND MAGNESIA CONTENT.

Analysis of Series XII (1:1:2 mixture), Table 3.

ORDER OF DURABILITY.		Al_2O_3.	MgO.	Total Al_2O_3 and MgO.	Factor Al_2O_3 divided by MgO.
Class.	No.				
I.....	14	5.61%	2.51%	8.12%	2.2
II.....	16	0.94	0.43	1.37	2.2
III.....	18	8.04	1.63	9.64	4.9
	12	8.50	2.58	11.08	3.3
	10	8.22	1.11	9.33	7.4
	2	7.21	2.74	9.95	2.6

TABLE 9.—CLASSIFICATION OF CONCRETE SPECIMENS, AFTER 5 YEARS OF EXPOSURE IN SEA WATER, IN THE ORDER OF DURABILITY, SHOWING THE EFFECT OF THE ALUMINA AND MAGNESIA CONTENT.

Analysis of Series XIII (1:2½:4½ mixture), Table 3.

ORDER OF DURABILITY.		Al_2O_3.	MgO	Total Al_2O_3 plus MgO.	Factor Al_2O_3 divided by MgO.
Class.	No.				
V.....	15	5.61%	2.51%	8.12%	2.2
	17	0.94	0.43	1.37	2.2
VI.....	9	7.21	2.74	9.95	2.6
	11	8.22	1.11	9.33	7.4
	13	8.50	2.58	11.08	3.3
VIII.....	19	8.04	1.63	9.67	4.9

The following are the important results developed as shown by Table 9:

(*a*) It happens that the two most durable specimens, as in Table 8, are those lowest in alumina content. Again, above a per-

centage of 7 in alumina content, no definite relation to durability is apparent.

(*b*) There is no apparent relationship of magnesia content, within the limits obtained, to durability.

(*c*) It is a curious condition that in the two best specimens the relation between the alumina content and the magnesia content is 2.2, the lowest of any.

VII			
VIII	19	Universal	6

A study of the preceding tables discloses the results of tests of Series I to VI, inclusive, and of Series XII and XIII of Table 3. There remain the special series, numbered VII to XI, inclusive.

Specimen No. 20, Series VII, is like No. 9, Series I, except that greater care was used in mixing the ingredients. The notes say: "Better mixture than commercial 1:3:6." The results indicate that this caused it to appear in the class above its mate, it being the fourth specimen above it in durability. This specimen was better than any other in the whole of Series XIII except No. 15, which appears to have been favored by a low alumina cement. The extra care used in mixing showed a decidedly beneficial result.

Specimen No. 21, Series VIII, was made like No. 9, but sea water was used in mixing. Unfortunately, this specimen was lost overboard.

and could not be recovered. At the end of 2 years it was in good condition and equal to No. 9, except for some slight roughness on the face. Evidently the use of salt water did no material injury, and was not as deleterious as the use of insufficient fresh water.

Specimen No. 22, Series IX, was mixed with 10% of hydrated lime substituted for an equal quantity of cement; otherwise, it was the same as No. 9. The durability tests show it to be two classes below No. 9, or the fifth below it serially in grade. Evidently, the lime allowed an earlier and more rapid erosion. This specimen is also poorer than eight of the other ten similar specimens in series, showing conclusively, so far as one specimen can, the deleterious effects of the hydrated lime when used in concrete immersed in sea water.

Specimen No. 23, Series X, contained the same ingredients as No. 9 with the addition of Sylvester wash. The water used in mixing contained soap solution made by dissolving light-colored soap in the proportion of 1¼ lb. to 15 gal. (125 lb.) of water. To each bag of cement was added 3 lb. of powdered alum. The total quantity of water in the batch was 288 lb. and of cement 5 bags. The addition of the Sylvester, according to the results of the tests, was decidedly harmful, as this specimen gave the poorest result of eleven similar ones. The concrete at the end of 5 years was in very bad condition.

Specimen No. 24, Series XI, is the same as No. 9, except that to each bag of cement there was added 4¾ lb. of clay. The clay was taken from a near-by excavation, dried, powdered, and mixed with each bag of cement. This specimen came through in good condition—better in fact than its mate, No. 9, and better than all the other specimens of a similar mixture, save only No. 15 (low alumina cement) and No. 20 (extra well-mixed concrete). There is evidence, therefore, that the addition of 5% of clay to the cement had a beneficial effect.

On September 11th, 1916, R. J. Wig, Assoc. M. Am. Soc. C. E., Engineer-Physicist of the Bureau of Standards, Washington, D. C., accompanied by L. R. Ferguson, Assoc. M. Am. Soc. C. E., representing the Association of Cement Manufacturers, visited the Boston Navy Yard in connection with studies of action of concrete in sea water. They were requested by the writer and kindly consented to examine the concrete specimens and to rate them in accordance with their condition at the time of the examination. It may be noted that the writer's rating of the specimens was made more

than 2 years before. Only very minor differences in the two sets of ratings occurred. In the specimens of greatest deterioration these differences can be explained by the changes in rate of deterioration during the 2-year period. The minor differences in the better specimens is explained by possible change in rate of deterioration or differences in judgment in rating two specimens nearly alike. The result as a whole is a very close confirmation of the original rating. The observers desired to note that their examinations of September 11th, 1916, were made on only the front faces and two sides of the specimens, as it was impossible to see the back faces without a small boat which was not available at the time.

The ratings, as made by Messrs. Wig and Ferguson, are as follows:

Group 1: Good condition, showing practically no deterioration; Nos. 14, 3, 16, 12, 10, 2.

Group 2: Satisfactory condition, showing little disintegration, but specimens are structurally sound; Nos. 6, 15, 18, 17.

Group 3: Poor condition, showing marked disintegration and, if part of a structure, in need of repair at once or at an early date; Nos. 1, 9, 5, 20; Nos. 4, 24, 11, 13.

Group 4: Bad condition and structurally unsound; Nos. 8, 23.

Group 5: Total failure; Nos. 22, 19, 7.

The bottoms of the specimens are at such an elevation that they are always submerged in sea water. The only chance for the examination of these parts of the specimen is when they are removed from their normal positions. On December 9th and 10th, 1913, the specimens were rehung from Pier 9. At that time the bottom of each specimen was examined, and no deterioration in the concrete was found to have taken place in any of the specimens.

The tops of all specimens are at such an elevation that they are very seldom submerged, and then only for a very short time. The concrete on the tops of all specimens appears to be in as good condition as when the specimens were originally constructed, and to show no deterioration, even in specimens that have eroded badly lower down. There are signs of some mechanical wear on the top edges of Specimens Nos. 7 and 22, but there is no appearance of deterioration of the concrete.

The 8-in. cubes formed at the time the larger specimens were made are now as follows: There are six 8-in. cubes on the quay wall adjacent to Pier 9 which are exposed to the weather in a roughly constructed box. No deterioration whatever is apparent in any of these specimens. There are five 8-in. cubes in a single box placed in the dock south of Pier 9 at the elevation of mean tide. These specimens are submerged approximately 12 hours each day. All the specimens except one show a disintegration of from 1 to 3 in. on the top, and the mortar on all but one of them is soft and crumbling to the touch, having the appearance of being dead. There is one specimen, however, that shows but little deterioration; the mortar remains hard, holding the aggregate firmly together. The top and one side only of each cube is exposed, the other sides being protected by the sides of the box and the adjacent cube. The 8-in. cubes that were originally suspended so as to be entirely submerged at all times have become lost owing to the breaking of the suspension cable, and no report can be made on them.

Conclusions.

The facts in connection with these tests have now been presented very fully, at the risk even of over-burdening the reader with details, but with the definite purpose in mind of allowing him to draw his own conclusions in the light of his own and of others' experiences. The series of experiments has been very complete in certain directions and was conducted from the start with unusual care, and some very valuable conclusions may be established. Other conclusions of less importance may also be drawn and be established with confirmatory experiences elsewhere. Great care must be exercised in applying these conclusions in predicting results elsewhere under dissimilar conditions, and the limitations under which these tests were conducted must be borne in mind.

It is desired to acknowledge valuable assistance rendered by employees of the Public Works Department, Navy Yard, Boston, in connection with observations and the preparation of this paper, especially Mr. E. S. Phelps.

APPENDIX A.

FORM OF AGREEMENT, INCLUDING SPECIFICATIONS, FOR TEST OF CONCRETE SPECIMENS, TO BE CARRIED OUT AT THE NAVY YARD, BOSTON, MASS.

This Agreement, mutually entered into between the United States Navy Department, party of the first part, and the Aberthaw Construction Company, a corporation of Maine, having a usual place of business in Boston, party of the second part, *Witnesseth*, that the said party of the second part agrees to build at the Boston Navy Yard a series of specimens to test the durability of concrete in sea water, said specimens to be built in accordance with the specifications hereto attached.

It is agreed that the party of the second part is not to put the Government to any expense in connection with these tests, and the party of the first part does not guarantee that the piers may not be disturbed as exigencies of the Navy Yard interests may require. As these experiments are a matter of considerable interest to the Government, its representatives will endeavor to continue the tests as long as it may be possible so to do.

The party of the second part agrees that all work shall be done in the presence of a representative of the Government, and that due notice of the intention to undertake work shall be given to the Commandant and to the Civil Engineer of the Yard in time for them to make arrangements for a representative to be present.

In witness whereof, the said parties have interchangeably signed and sealed this agreement on the 28th day of December, 1908.

FRED THOMPSON,
Civil Engineer, U. S. N.
ABERTHAW CONSTRUCTION CO.,
by L. C. Wason, Pres.

SPECIFICATIONS FOR TEST SPECIMENS OF CONCRETE TO BE IMMERSED IN SEA WATER BY THE UNITED STATES NAVY DEPARTMENT, DECEMBER, 1908.

Object.—The object of these tests is to determine what the action of sea water is upon concrete, both as regards climatic conditions and chemical action. The tests are to be made as nearly as possible in conformity with usual commercial work, in order to be comparable in all respects with actual work.

How Done.—The specimens are to be built in accordance with the requirements of the Navy Department, and under their direct supervision, and in accordance with the following detailed specifications.

They are to be built in molds in the sea or in such other position as may be directed, and exposed for easy inspection and for photograph-

ing. They shall be marked so as to be easily identified, and a careful record of the materials and methods used shall be kept for each specimen.

Specimens.—The piers shall be made 16 in. square and 16 ft. long, in such a position that the lower 2 ft. shall be permanently immersed in sea water; thus it is improbable that the top will ever be immersed.

There are to be twenty-four (24) piers, as follows: In the first series of nine specimens, a standard average composition Portland cement shall be used throughout, which shall pass the standard specifications of the American Society for Testing Materials, as required by the Navy Department.

No. 1 shall be made of 1 part of cement, 1 part of sand, and 2 parts of stone, and mixed quite dry.

No. 2 shall be made of the same mixture as No. 1, and mixed with sufficient water to make the concrete plastic.

No. 3 shall be the same as No. 1, but mixed very wet.

No. 4 shall approximate 1 part of cement, 2 parts of sand, 4 parts of stone, but shall be proportioned so that, after a mechanical analysis of the materials, the excess of cement over the voids of the sand shall be 10%, and the excess of mortar over the voids of the stone shall also be 10 per cent. It shall be mixed quite dry.

No. 5, same proportions as No. 4, but mixed plastic.

No. 6, same proportions as No. 4, but mixed very wet.

No. 7, 1 part of cement, 3 parts of sand, and 6 parts of stone. Mixed quite dry.

No. 8, same as No. 7, but mixed plastic.

No. 9, same as No. 7, but mixed wet.

No. 10 shall consist of a Portland cement which is free from iron. One specimen shall be mixed, of the proportions 1:1:2, quite wet.

No. 11 same cement as No. 10, 1:3:6, wet.

No. 12 commercial Portland cement high in alumina, mixed 1:1:2, wet.

No. 13 same cement as No. 12, 1:3:6, wet.

No. 14 of a commercial Portland cement low in alumina, 1:1:2, wet.

No. 15 same cement as No. 14, 1:3:6, wet.

No. 16 of an iron ore cement practically free from alumina, 1:1:2, wet.

No. 17 same cement as No. 16, 1:3:6, wet.

No. 18 of Universal cement, 1:1:2, wet.

No. 19 same cement as No. 18, 1:3:6, wet.

No. 20 shall consist of the same materials and proportions as given for No. 7, but shall be most thoroughly well mixed (much better than commercial mixing), at the same time being quite wet.

No. 21 shall be the same as No. 7, but mixed with sea water, quite wet.

No. 22 shall be mixed of $\frac{9}{10}$ by weight of one part of standard Portland cement as No. 7, $\frac{1}{10}$ part by weight of hydrated lime, 3 parts of sand, 6 parts of stone, mixed wet.

No. 23 shall be of the materials given for No. 7 but in addition shall contain Sylvester mortar hereinafter described, mixed wet.

No. 24 shall be of the materials in No. 7 and in addition shall contain 5% by weight of the cement of finely pulverized clay, mixed wet.

In addition, there shall be fifteen cubes, 8 in. on each side, of 1 part of standard Portland cement, 1 part of sand, and 2 parts stone; and fifteen others of the same cement, mixed 1:3:6. One-third of these, after being thoroughly set, shall be permanently immersed in water; another third shall be supported at about half tide; and the rest shall be kept permanently dry but exposed to the weather.

There shall also be made briquettes, of the same cements and proportions of mortar as above described for concrete, of such number that they can be tested at intervals covering a period of years, some of which shall be kept in the laboratory, some exposed to the same conditions that the cubes will have; and enough briquettes shall be made of standard sand to compare the relative strength between standard and the materials actually used.

Testing of Materials.—All cement shall be thoroughly tested for all physical properties, and shall be subjected to chemical analysis. The sand shall be subjected to a thorough mechanical and physical analysis to ascertain the relative sizes of its grains and the quantity of foreign matter which it contains, if any. The same tests shall be applied to the stone. The various ingredients, such as sea water, hydrated lime, Sylvester mortar, and clay, shall be tested, in order that the exact nature of the material may be known.

Sand.—The sand shall be of a good quality, commercial bank sand, clean, coarse and sharp, as free from all impurities and foreign matter as can be obtained commercially. The stone shall be of trap rock which shall have passed a 2-in. ring and have been retained on a $\frac{1}{2}$-in. ring. It shall be as free from dust and dirt as commercially practicable.

Mixtures.—All materials shall be proportioned by volume, as given above for each specimen. A cubic foot of cement shall contain 100 lb. The sand and stone shall be measured on the basis that a barrel of cement contains 380 lb. net and measures 3.8 cu. ft. Samples of the sand and stone shall be weighed so that the proportion by weight (as well as by volume) will be known.

The quantity of water to be used shall be accurately measured for each batch, and shall be proportioned by experiment, so that the dry specimens shall just fail to show moisture when tamped in place; the

plastic specimens shall just barely begin to quake when tamped; and the wet specimens shall be proportioned so that the mortar will flow easily off the blade of a shovel and shall be wet enough to flow readily into place without being spaded or tamped.

The Sylvester mortar shall be mixed as follows, as given in Gillette's "Hand Book of Cost Data", pages 389 and following: A light-colored soft soap shall be dissolved in water, 1¼ lb. to 15 gal. of water, and 3 lb. of powdered alum shall be mixed with each bag of cement. After all the materials of the concrete are thoroughly mixed dry, water containing the soap in solution shall be used to mix the materials wet to the proper consistency.

Mixing.—All materials shall be thoroughly mixed in a batch concrete mixer of approved type. They shall be fed into the machine as quickly as possible, and shall remain for 2 min. after the last ingredient is added. For the specimen which is to be extra thoroughly well mixed, the material shall remain in the mixer for 12 min.

If the weather is cold, all frost shall be removed from the sand and stone by heating before the materials are placed in the mixer.

Placing.—The concrete, after mixing, shall be placed in the forms as quickly and continuously as possible, and, after proper tamping, shall not be again disturbed. In no case shall concrete which has been allowed to stand for more than ½ hour be used, and in no case shall ½ hour elapse between placing two batches of concrete in the same mould.

Forms.—The forms shall consist of planed and matched spruce lumber, so that they may be as tight as possible, and shall be braced so thoroughly as not to spring under the pressure of green concrete. The forms shall be left on for such a length of time that there shall be no damage to the concrete when they are removed. The Inspector shall be the judge as to when it is proper to remove the forms.

Reinforcement.—The columns shall be reinforced with an embedded steel bar, about § in. square, which shall be bent into a U-shape and run throughout the length of the big specimens near two diagonally opposite corners, and the loop shall project a sufficient distance above the top of column to permit of its being easily hooked in case it is desired to remove it.

A hole, 3 in. in diameter, shall be cored in the upper 8 ft. of each specimen, to permit of examination from time to time to see if water has penetrated through the walls of the concrete to the hole.

Protection.—After the specimens are cast, they shall be protected from freezing, as far as possible, until they have set for a period of at least 5 days, and, after the forms have been removed, they shall be thoroughly and substantially braced, so that there shall be no danger of their tipping over.

DISCUSSION

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—This is an interesting paper on an interesting subject, and should bring out a full discussion from experience in actual work.

The author calls attention to the fact that a mixture of one part of cement to two parts of sand gave a better test than the mixtures which were not so rich in cement. This is undoubtedly due to the fact that a 1:2 mixture comes nearer to having the voids of the sand filled with cement than a poorer mixture, and, of course, a concrete with all the voids filled has a better chance of resisting the effects of frost and of any injurious chemical which may be in the water or air; and probably explains why the greatest damage to concrete is generally between high and low water.

Some years ago the speaker built a breakwater, off New Rochelle, which is subjected to storms with the full sweep of Long Island Sound behind them. A rock fill was used, up to the low-water mark, the depth of water at low water being 25 ft. at the outer end.

From low water upward the stones were carefully placed to a height of 14 ft. (except for the outer 50 ft.), on top of which a 12-in. concrete coping was placed, as individual stones would have been displaced by the storms, although the top of the breakwater was 9 ft. above ordinary high tide.

At the outer end, for 50 ft., the built-up stonework was only 8 ft. above low water, on top of which was placed a concrete block, 7 ft. high, 10 ft. wide on the base, 5 ft. on the top, and 50 ft. long; a small quantity of reinforcement was used.

This breakwater has stood successfully the severe storms of the Sound for some 11 years; but this year it has been noticed that a small quantity of the concrete has seriously deteriorated for a foot or so at the bottom and for about a foot in depth.

It was a little surprising, however, that this destruction occurred on the inside or sheltered portion of the breakwater, instead of outside, where it was exposed to the storms. This may have been due to the fact that on the exposed side of the breakwater any injurious chemicals from sewage, etc., would be washed away instead of remaining in place, as they would on the sheltered side.

It has been found impossible to get a concrete to withstand the action of impure, hot water, in some power-plants. In one case the efforts have been abandoned, and a wooden lining has been substituted for the concrete.

It would seem that the three principal causes for disintegration of ordinarily good concrete in sea water are: first, too coarse a mixture,

* New York City.

in which the voids of the sand or stone are not filled—thus allowing chemicals to accumulate; second, alternate freezing and thawing, which do far more damage when the voids are not filled; and third, the action of injurious chemicals assisted by heat. Mr. Thomson.

The remarks in the discussion about sand recall an attempt of a railroad contractor, many years ago, to make the railroad haul free of charge for 110 miles a fine beach sand, because the local sand appeared to contain too much loam. The speaker made three sets of tests: first, with regular testing quartz; second, with the loamy sand; and third, with the fine beach sand. The tensile strength developed by the briquettes of the quartz and loamy sand were almost the same, and those made with the clean but fine sand gave only half the strength of the others. As strength in the concrete was what was wanted, the work was finished with the loamy sand.

J. J. YATES,* ASSOC. M. AM. SOC. C. E.—The question of the action of sea water on concrete is of great importance, as it affects the permanency of such a large number of important structures which have been, or may be, built in sea water. This paper adds much valuable information on a subject that has received far too little study. Mr. Yates.

The speaker, however, thinks that one important phase which has not been considered is injury to concrete structures by floating ice or floating débris, resulting in the breaking up of the surfaces and the exposure of the interior concrete to the action of sea water.

From observations of existing structures, extending over a period of about 15 years, the speaker is led to the opinion that, in setting, a surface is formed on concrete which will resist successfully the action of sea water on the cement; and that, as long as this surface is maintained in good condition, no destructive action due to sea water may be expected. In other words, he is of the opinion that concrete surfaces are first injured or broken up by drifting material, and that, after they are thus broken up, the concrete is not able to resist the action of the sea water. Observations indicate that this action, after it once starts, continues, and is accelerated by the wearing away of the disintegrated surfaces by drifting ice and other material, or by the alternate freezing and thawing of the concrete surfaces between tides. By one of these means, the disintegrated concrete is removed, continually exposing a fresh surface to the action of the sea water.

As examples of the action of sea water on concrete, the following are given:

The concrete masonry of the old center piers of the Hackensack and Passaic River Bridges of The Central Railroad Company of New Jersey were constructed about 1870 of Rosendale cement. The

* New York City.

Mr. Yates.

concrete of these piers was deposited in a circular, wrought-iron, floating caisson, which was sunk in position to a depth of about 12 ft. on a previously prepared pile foundation. About 1888 or 1889 the iron superstructure was renewed, making use of the old piers. When inspected about 1902 it was found that the iron caisson had completely disappeared, to a depth of several feet below low water, and that the concrete had been eaten away between high and low water to a depth, in some cases, of about 2 ft. These piers were repaired by patching with concrete behind a steel plate band extending around each pier.

The piers were not exposed to drifting material, as they were protected or practically enclosed by pile and timber fenders of a type generally used at draw-bridges. Considerable trouble was experienced, however, from ice forming around the piers. In fact, during extreme high tide conditions, the operation of the lower of the draw-bridges was seriously interfered with by ice clogging the bearing wheels on the center pier.

In 1912 both the substructure and the superstructure were removed, and temporary structures were built at one side for the purpose of building new bridges.

During 1903 to 1905 The Central Railroad Company of New Jersey replaced its draw-bridge over Newark Bay, about ¾ mile from its mouth or junction with Staten Island Sound, with two bascule spans. The seven concrete piers required were deposited in air within wooden floating caissons which were sunk to a depth of about 30 ft. on prepared pile foundations. Sea water was not allowed to come in contact with the concrete until it had had time to become thoroughly set.

The concrete was composed of 1 part of cement, 3 parts of sand, and 5 parts of 1½-in. broken trap rock. The following is a representative test analysis of the cement used:

Sulphuric acid	1.38%	Magnesia	1.54%
Gravity	3.06	Water and steam tests	O. K.
Initial set	1 hr.	Hard set	4 hr. 30 min.
Residue, No. 200 sieve	27.5%	Residue, No. 100 sieve	8.0%

One-day test	385 lb.
One-week test	716 lb.
One-week test, sand	315 lb.

The concrete was deposited under the supervision of experienced men, who stated that all the piers were treated in the same manner.

Shortly after the timber caisson was removed, Pier 5 was injured between high and low water by a floating barge. This injury was repaired by patching with concrete. Examinations of this pier in 1909 showed that the patch had disappeared entirely, and that the concrete

was being eaten away gradually between high and low water at the point of injury. All the remaining piers except two showed some deterioration of the concrete between high and low water. In the case of Pier 5 the concrete was eaten away to a depth of 20 in. Two piers showed practically no deterioration. An examination by a diver in 1909 showed that there was no deterioration of any of the piers below a point about 1 ft. below mean low water. From observations, the piers most affected were those which had the greatest exposure to floating ice or drift. Mr. Yates.

Attempts were made to get samples of the disintegrated concrete for the purpose of making a chemical analysis to determine, if practicable, the action of the sea water. This was found impracticable, but when the samples were first removed and still wet, a large number of crystals of a white salt were visible, and these seemed to disappear entirely as the concrete dried out.

These piers have been repaired several times—once with a cement gun, which latter repair lasted about 4 years. The repairs have somewhat retarded the disintegration of the concrete, but the destructive action has been found to be practically continuous. It is very noticeable that the action is not general over the whole surface, but is rather confined to spots, such as the injured section of Pier 5.

Another example may be cited, not particularly for the disintegrating action of the sea water, but rather on account of the fact that a sample of the white salt, mentioned in reference to the Newark Bay Bridge, was obtained and analyzed; this is the bridge of The Central Railroad Company of New Jersey over the Shrewsbury River about a mile from its outlet in Sandy Hook Bay, and built in 1913. Ten piers were constructed in sea water, and of these, two showed signs of failure about a year after they were built. These piers were rebuilt, and an investigation into the cause of the failure developed the fact that, in both of them, the concrete of the foundations, which had been deposited in water with a tremie, had been deposited at low tide, when the chute to the tremie was very flat. The concrete mixer had been on a floating barge, and the low tide had caused the flat condition of the chute which resulted in the concrete being mixed very wet and the tremie not being kept full of concrete during the process of depositing.

The concrete foundations of these piers failed completely, and when removed showed stratification, consisting of alternate layers of a putty-like substance and of sand and gravel with a little cement, or rather, a very weak mixture of concrete. Samples of this mixture were taken, and the small crystals of white salt were plainly visible when the concrete was first removed and before it had time to dry out. Enough of this white powder was collected, and an analysis was made

Mr. Yates.

by Mr. C. M. Chapman, Engineer of Tests, of Westinghouse, Church, Kerr and Company, a copy of which is as follows:

"We have made an analysis of the sample of white powder which was scraped from the sample of disintegrated concrete from the Shrewsbury River bridge pier, with the following results:

"Free Silica	$Si\ O_2$	57.64%
Alumina	$\left\{ \begin{matrix} Fe_2\ O_3 \\ Al_2\ O_3 \end{matrix} \right\}$	7.44
Calcium	Ca	6.83
Magnesium	Mg	8.66
Chlorides	Cl	1.82

"The large amount of silicia is undoubtedly due to the grains of sand which were scraped off the concrete with the sample. Eliminating the silica from consideration, we find that the sample is made up of approximately equal parts of magnesium, calcium, and iron alumina oxides. The magnesium is somewhat in excess of the calcium, which indicates a transfer of the calcium and magnesium bases between the cement in the concrete and the salt in the sea water. The magnesium of the sea water replaces the calcium of the cement. This action can only take place where the sea water has free access to the cement, or, in other words, at points where the concrete is quite porous. In a dense concrete such action could not take place, or would be so slow that it would be almost negligible."

At the south or up-stream end of one of these piers, when examined about 6 months ago, there was disintegration over a small area to a depth of about 2 to 3 in. between high and low water. This end of the pier is very much exposed to damage from floating ice.

Another example of the deterioration of concrete in sea water is one of the piers of the bridge of The Central Railroad Company of New Jersey over the Elizabeth River at Elizabethport, N. J. Due to delays which were beyond control, it was necessary to deposit the concrete for these piers in freezing weather. Parts of the surfaces of the piers were injured slightly by freezing, which resulted later in a peeling of the surfaces. These surfaces were patched with a cement gun, and have shown no further peeling, with the exception that the patching on the down-stream end of one of the piers has fallen off. Where the injured surface of this pier is between high and low water the concrete has disintegrated to a depth of from 4 to 6 in.

The water of this stream is salt, but is apt to carry a large mixture of sewage and fresh water. The pier surfaces are covered with slime between high and low water, but, with the exception noted, show no deterioration such as might result from the action of salt water.

In regard to the construction of the New Hackensack and Passaic River Bridges by The Central Railroad Company of New Jersey in 1912-14, it may be of interest to note that, due to experience with

the disintegration of concrete in sea water, it was decided to build those portions of the piers between high and low water with a granite facing, backed up by a concrete interior. This granite facing was carried from a point 2 ft. below mean low water to a point 2 ft. above high water. Mr. Yates.

Practically the whole of the 12 000 cu. yd. of concrete in the foundation of these piers was deposited in water with drop-bottom buckets. The channel piers extended to a depth of 30 ft. below low water, and the concrete was deposited continuously within timber coffer-dams up to a point 2 ft. below low water. About a day after the completion of the concrete, the water was pumped down, the laitance was removed from the upper surface, and the construction of the remaining portions of the piers was carried on in the air.

The concrete was composed of 1 part of Portland cement, 2 parts of washed Cow Bay sand, and 4 parts of washed and graded gravel.

In experimenting with different concrete aggregates, it was found that when Cow Bay sand and gravel were used, 2 to 3 in. of laitance would result in depositing a depth of 15 ft. of concrete under water. When Cow Bay sand and 1½-in. broken trap rock (dust screened out) were used, the result was about double that quantity of laitance. For this reason practically all the work was done with the gravel.

Examinations of the under-water surfaces by a diver, shortly after the completion of the structure, developed no defects, except that on one of the piers there was found a wedge-shaped horizontal band of laitance, from 4 to 6 in. wide, a section of which the diver was able to remove to a depth of about 4 in. Investigations showed that this band of laitance was due to several days' stoppage of the work of depositing the concrete at this level, and that, although attempts had been made to remove the laitance with a clam-shell bucket and the help of a diver before the depositing was again started, the efforts were not entirely successful.

Annual general inspections of all the structures on the Central Railroad are made by the Bridge Engineer, and no disintegration similar to that found in salt water has ever been observed in concrete piers in fresh-water streams, although in many cases the concrete is exposed to damage from floating ice. Concrete surfaces have been found injured (probably by floating ice), but no disintegration has taken place. This rather disproves the theory that the disintegration of concrete in sea water, between tides, is due solely to the alternate freezing and thawing of the concrete.

The result of the speaker's experiences with the structures cited leads him to believe that concrete can be used safely in sea water, provided there is no danger of the surfaces being injured by floating material. Where such action is at all likely to take place, it has been

Mr. Yates. decided to use a stone facing backed up with concrete. The speaker has no hesitation in using properly deposited concrete to a point 2 ft. below low tide, or to a height that is below any likelihood of injury by floating material.

Mr. McClintock. J. R. McCLINTOCK,* M. AM. SOC. C. E.—The speaker had an experience, at Clarksburg, W. Va., with disintegration of some concrete beams across the top of an open coagulating basin. These beams are normally above the water level, but at times, owing to careless operation of the pumps, they are alternately submerged and exposed, causing in cold weather very severe freezing conditions.

The basin was constructed 7 years ago, and after about 5 years probably two-thirds of these beams were almost completely disintegrated, the concrete looking practically like a loose shale. The other beams, although under the same conditions, were practically intact.

As far as known, there was no difference in construction methods. They were all built by the same gang, with the same foreman, and presumably of the same materials. It is possible, however, that in some of these beams use was made of a local stone which is subject to disintegration when exposed to the weather. There were some delays in the shipment of the hard limestone regularly used, and it is very likely that some of the poor local stone may have been used, in order to avoid waiting.

The contractor on this work had rather a disappointing experience with the local stone. In excavating for a reservoir, probably 4 000 or 5 000 cu. yd. of stone were piled up to be used later for concrete. After this material had remained piled up nearly a year, it was found to have weathered to almost a soft clay. When taken out it appeared to be a good hard stone.

The other concrete structures at Clarksburg, including a filter plant and a 1 000 000-gal. concrete tank, were substantially impervious to water, as judged by leakage measurements, and it is puzzling to understand just why the beams proved to be so porous as to allow the entrance of water to cause their disintegration.

There is another factor which should be mentioned. The river water receives a great deal of acid mine waste, and the sulphur compounds may have had some effect on the concrete. This, however, would not explain a selective action on some parts and not on others. Probably the best explanation is that poor stone was used in a portion of the beams, and good stone in the rest. The stone was of a nature between a shale and a sandstone. The different strata change gradually from a true shale into a sort of stone locally called sandstone.

* New York City.

S. B. WILLIAMSON,* M. AM. SOC. C. E.—Before the construction of the locks on the Panama Canal, there were several independent investigations as to the effect of sea water on concrete, and all the information obtainable was gathered at that time. According to the speaker's memory, the failures recorded were due largely to porous or pervious concrete. On the strength of this information, the engineering authorities on the canal agreed to use concrete in the lock construction; and in the lower parts of the locks that were subject to sea water a richer mixture was used. Mr. Williamson.

At Miraflores, where there is a 20-ft. tide, and the lock gates are about 83 ft. high, an interesting condition developed: It was found that the difference in the weight of the salt water on the lower side and the fresh water on the inside of the gates made it possible to have a head of about 18 in. on the lower side of the gates, tending to force them open when the lock was full.

In order to discover a means of overcoming this, a number of experiments were carried out, and it was finally ascertained that, by turning up the lower ends of the culverts so as to discharge at a certain elevation, the inter-mixture or diffusion took place in such a way as to equalize the pressure heads.

Thus far, the concrete in the locks has shown no signs of disintegration. There has been some disintegration, however, in the concrete docks built at Balboa. These are reinforced docks, supported by reinforced concrete cylinders, and some of the floor girders are partly submerged at extreme high tide. These show some disintegration, especially where cracks have appeared, but as yet there is nothing serious.

Great care was taken in the composition and placing of the concrete in the locks, particularly where they will be subject to sea water, and the speaker believes that the concrete is impervious and will not be readily attacked.

WALDO C. BRIGGS,† M. AM. SOC. C. E.—There is one point which the speaker would very much like to have developed. If "the addition of clay to the cement had a slightly beneficial result" with the concrete subjected to such unusual conditions, why not modify the customary specification for sand, requiring it to be "clean and sharp", to read "clean and sharp, free from dirt, loam, mica, and organic matter, and shall contain not more than 5% by volume of clay"?‡ Mr. Briggs.

It happens sometimes that what appears to be a very good grade of sand is encountered in excavation made in connection with construction work; but if this sand contains clay, it necessarily is rejected if the specifications require it to be clean.

* New York City.
† Long Island City, N. Y.
‡ Bureau of Sewers, New York City.

Mr. Bilyeu. CHARLES S. BILYEU,* ASSOC. M. AM. SOC. C. E.—A curve of maximum density, or an ideal curve for the combination of sand and aggregate, has been plotted from the results of an extended series of tests by William B. Fuller and Sanford E. Thompson, Members, Am. Soc. C. E., at Jerome Park Reservoir, New York City, in 1902-04.

The speaker's criticism of specifications refers particularly to those for reinforced concrete buildings. It is true that such specifications are frequently prepared in architects' offices, and that engineers are not responsible for them. They generally cover adequately the testing of the cement, but rarely contain any requirement for the analysis of the sand and aggregate.

The speaker has been called on, from time to time, to make tests of materials (particularly sand) used in large and important buildings. In several instances the sand has been found to contain an abnormally large percentage of very fine grains, and to be otherwise unsuitable for use in work of such character. Tests of this nature are usually arranged for only after the work is well under way and after it has been found that the concrete has not developed proper strength.

In the speaker's opinion, careful sand and aggregate analyses are very important investigations, and are absolutely necessary for safe and economical concrete construction.

Mr. Day. W. E. DAY,* ASSOC. M. AM. SOC. C. E.—In line with the discussion of sand mixtures, an incident on some construction work during the past season might be described. A sand pit was opened, about 2½ miles from the work, which contained a sand of excellent quality. The testing laboratory reported that it was very clean, and that the percentages of various sizes were such as to make it an almost perfect sand for concrete.

On account of the long haul, the experiment was made of mixing this pit sand with a very fine beach sand, containing considerable loam, which was right on the works. Test cubes and briquettes were made with pit sand containing from 0% to 45% of beach sand. These cubes and briquettes were tested after being stored 30 days, and the results showed that adding up to 30% of beach sand improved the strength of the concrete, as compared with concrete made from the so-called perfect sand.

Mr. Ridgway. ROBERT RIDGWAY,* M. AM. SOC. C. E.—It is generally agreed that the grading of sand is very important. A well-graded sand containing a small quantity of clay is preferable to a poorly-graded sand which is free from impurities, particularly if the sand is uniformly fine. It is well, however, to reduce the quantity of clay and other impurities to a

* New York City.

minimum, and what one should strive to get is a clean, well-graded sand. The speaker does not agree with those who have advocated the use of a small quantity of clay to increase the density of the concrete. It is better to omit the clay and substitute a little more cement, in order to secure this density, thereby increasing the strength of the concrete as well. If the clay appears as lumps in the sand, it is obviously more objectionable, as Mr. Fuller states, than if in the form of a powder. The holes often seen in the surfaces of cement walks and in the faces of concrete walls are generally caused by the dissolving of lumps of clay which were incorporated in the mix. Mr. Ridgway.

Mention has been made of limestones as concrete aggregates. The use of limestones was not permitted in the Catskill Aqueduct specifications for pressure-tunnel lining because of their solubility. This was the result of a careful study of the subject by the Designing Division of the Board of Water Supply before the specifications were prepared. It was found, in a number of instances, that concrete had disintegrated, due to the solubility of the coarse aggregate. A notable example cited was that of the Thirlmere Aqueduct for the City of Manchester, England. In this case, as the speaker understands it, an almost pure limestone was used, and the soft water in the Aqueduct dissolved it to such an extent that the concrete was badly disintegrated. In most works, however, limestones are not prohibited; for example, the Public Service Commission specifications for subway construction in New York City permit the use of "Sound, hard, broken limestone."

In driving the new rapid transit tunnel under the East River from Old Slip, Manhattan, last year, the shield working under compressed air encountered the concrete foundation of the wall at the river bulkhead line. This concrete had been deposited in bags under the salt water by the Department of Docks and Ferries of New York City about 10 years before. The mix was said to be 1:2:5, and it was found to be in excellent condition, as sound and dense as though it had been placed behind forms in the dry. The burlap of the bags was still there, but the concrete was bonded so well that it looked like good mass concrete. There was no sign of any disintegration.

GEORGE W. FULLER,* M. AM. SOC. C. E.—This discussion brings out four leading points: First, that imperviousness of concrete is a *sine qua non* for structures subjected to a fluctuating water line; secondly, laitance must be carefully guarded against; thirdly, there is the question of temperatures, in relation to disintegration by alternate freezing and thawing; and, fourthly, there is the question of what may be brought about by organic matters and their decomposition to form acids under putrefactive processes. Mr. Fuller.

* New York City.

Mr. Fuller.

Sanitary engineers know well, in connection with water-works and sewerage structures, what porous concrete may signify, especially as to the stability and integrity of structures above and near the flow line, as ordinarily seen.

Mr. McClintock has given some interesting observations on concrete sedimentation basins of the water-works plant at Clarksburg, W. Va. This shows what freezing and thawing may do, in the absence of any acids or organic matter to decompose the structures, where concrete, probably not as impervious as it should be, is subject to the various influences of the elements, especially where there is a fluctuating flow line.

Now for a few words in respect to the fourth element, and that is the disintegration of concrete, mortar, or brick, under those circumstances where the decomposition of organic matters of sewage or polluted water may bring about substances which produce acids.

That is probably an old story. It has been debated, year in and year out, in relation to the question as to whether concrete is as good as brick for large sewers.

It is a fact that the organic matters contained in sewage under some circumstances will undergo bacterial decomposition, and that the sulphur compounds in the organic matters will be changed to sulphureted hydrogen, in the complete absence of dissolved atmospheric oxygen, and in the presence of the right kinds of bacteria which ordinarily grow there. It is a further fact that, when bacterial agencies bring about what are commonly called putrefactive changes, sulphureted hydrogen and other products of putrefaction may be obtained from mineralized sulphur compounds, such as sulphate of lime or magnesia, and found in cement, fresh water, and sea water.

Sea water is so highly mineralized that we probably do not realize what opportunities there are for the formation of compounds of a dissolving nature. Neither do we know what inter-reactions may produce, in conjunction with putrefaction, as to solvents from magnesium chloride and other neutral salts of a supposedly stable and non-corrosive nature with respect to concrete.

The formation of sulphureted hydrogen does not cause an appreciable corrosion of fairly good concrete below the minimum water line of a sewer, septic tank, or pier of concrete, so far as the speaker's observations and studies go. Even in septic tanks, he has heard of only one instance of serious disintegration of concrete in the lower part of the structure, and that was in the case of a tank in the arid regions of the Southwest.

Sulphureted hydrogen must be converted into sulphuric acid in order to develop corrosive properties. This is effected when the gaseous sulphureted hydrogen rises above the water, meets the oxygen of the

air, and in the presence of moisture. This is why sewers, septic tanks, and piers are disintegrated above and not below the flow line. Of course, this solvent action varies in intensity with the porosity of the concrete, effect of freezing, etc. Mr. Fuller.

The outfall sewer of Los Angeles showed disintegration of mortar and signs of deterioration of brick in manholes beyond the main siphon, but not below the flow line. When the atmosphere with its oxygen was excluded, this disintegration was stopped to a surprisingly satisfactory extent.

Much sulphureted hydrogen does not escape into the atmosphere, as it combines with iron salts to form the black ferrous sulphide of iron, which gives liquids in process of putrefaction their black characteristic appearance. This is why the sludge of septic tanks is black, and why the sediment in pump wells and settling basins is black, as was reported in detail by the speaker some 20 years ago in his water purification investigations at Cincinnati.

Laitance should certainly be kept within reasonable limits, otherwise undesired results are to be expected. Undoubtedly, the pendulum is swinging back from the very wet mixes of recent years toward the dry mixes of 20 years ago. However, the mix should not be so dry as to make it problematical as to removing entrained air from the pores of the concrete.

It is feasible to use sand with a moderate quantity of silt or clay without vitiating the integrity of a structure, if that fine material can actually be used as filling uniformly a certain portion of all voids of the sand as a substitute for cement; but if such silt or clay is in lumps or is otherwise irregularly and improperly dispersed in the voids of the sand, the programme becomes invalid.

Fine material is objectionable if it occurs as a coating on the sand particles, as it weakens the concrete; or if it contains sufficient organic matter to interfere with the setting of the concrete; or if it is flaky or of such character as to produce lumps, on mixing the concrete.

On the other hand, fine material may add materially to the imperviousness and density of the concrete. This is a function of the mix of concrete, the nature and quantity of the fine material; the percentage of voids in the sand; and the relative size and shape of the sand particles.

As Mr. Ridgway says, clean sand filled with an excess of cement has marked advantages in the direction of safety; but this is not always practicable in some localities, or worth its cost in others—as compared with using sand with fine material in it.

At York, Pa., the local building sand is a crushed rock containing 10% or more of fine material passing a 100-mesh sieve. It was used with satisfaction on several hundred thousand dollars worth of work

Mr. Fuller. on outfall sewers, pumping station, and sewage treatment plant. Apparently, this material did not form lumps. Its use saved the needless added cost of obtaining other sand transported from a long distance. However, this is a procedure which ought not to be adopted without careful investigation in each local case.

Mr. Rhett. A. H. RHETT,* ASSOC. M. AM. SOC. C. E. (by letter).—The subject of the disintegrating action of sea water on concrete has received much discussion among engineers, and the results of the tests at the Boston Navy Yard, as described by Mr. Bakenhus, seem to the writer to throw some light on the subject and point to one primary and basic cause of disintegration. This is the porosity of the concrete.

In *Technologic Paper No. 12*, of the Bureau of Standards, on the "Action of the Salts in Alkali Water and Sea Water on Cements", it is stated that "a hydraulic cement is readily decomposed if intimately exposed to the chemical action of various sulphate and chloride solutions", if these solutions are of sufficient strength.

The most conspicuous result of these tests is, that whatever disintegration did occur, occurred approximately between high and low water. It is quite obvious that, if the concrete is porous, the pores would be filled with water at high tide, that the salts of the water would be deposited by evaporation during the recession of the tide, and that this process would be repeated until the solution in the pores would become of sufficient strength to give rise to this chemical action. It must be, therefore, that if a concrete is porous, it is subjected to a much stronger chemical action between high and low water than elsewhere, due to this accumulative concentration; on the other hand, if it is non-porous, no such concentration can occur. It is true that evaporation is necessary for the precipitation of the crystals the increase of which in volume causes the actual disruption or disintegration of the concrete, but the unaffected pieces were subjected to the same alternate wetting and drying as the affected ones, and this alone cannot account for the erosion. It seems possible, also, that sea water in its normal condition is not sufficiently strong in sulphates and chlorides to produce chemical action.

The writer has re-stated the conclusions drawn by Mr. Bakenhus on the results of the tests, which conclusions are substantiated by a detailed examination of those tests, and it will be seen that in each case these conclusions can be interpreted as confirmatory of the proposition that the disintegration was more or less proportional to the porosity of the concrete.

"(*a*) That the 1:1:2 mixture is superior to the 1:2½:4½, and that the 1:2½:4½ is, in turn, superior to the 1:3:6."

* New York City.

Mr. Rhett.

It requires no exposition to confirm the statement that the richer the mix the less porous the concrete, with similar conditions of mixing and placing.

"(*b*) That the wet mixtures are superior to the dry."

The tests made by the Bureau of Standards on the hydration of Portland cement, as reported in *Technologic Paper No. 43*, show that there is a latent element which in many cements does not begin to hydrate until 28 days or later, but if then continued in the presence of water, it hydrates with a large increase in volume and with an amorphous structure. It is obvious that this action tends to close the pores of the concrete by filling them with this amorphous material, and that this inert, but most important, action cannot occur except in a wet concrete which is not permitted to dry out too quickly. In the present instance, it was specified that the forms should be "matched" and "as tight as possible" so that the water in the wet mix was retained.

In *Technologic Paper No. 58*, of the Bureau of Standards, on the "Strength and Other Properties of Concrete as Affected by Materials and Methods of Preparation", it is shown from the tests made that, with a given mix, the resulting compression strength of the concrete was about 100% greater with 10.5% of mixing water than with 6.5%; that it was about 25% greater when cured in a moist atmosphere than in the open air; and that the compressive strength is proportional to the density.

"(*c*) That the effects of magnesia and alumina in varying proportions are not very marked, and follow no apparent law, although the two most durable specimens are those lowest in alumina content."

This conclusion is confirmed by *Technologic Paper No. 12*, previously referred to, which states that "contrary to the opinion of many, there is no apparent relation between the chemical composition of a cement and the rapidity with which it reacts with sea water when brought into intimate contact"; and that "the quantity of alumina, iron, or silica present in the cement does not affect its solubility."

"(*d*) That extra care in mixing produced decidedly beneficial results."

The experiments of Michaelis, Cabolet, and others have shown that when cement is continuously mixed with water an increase in volume as much as seven hundred-fold may occur. Such an increase in the volume of the cementitious material would tend to fill the natural voids in the aggregates and make the concrete non-porous.

"(*e*) That hydrated lime was of no benefit, but rather a detriment."

To refer again to *Technologic Paper No. 12*, it is shown that lime is the element of the cement that is attacked by the sulphates and

Mr. Rhett. chlorides of the salt water. This action is shown to be even more pronounced with set than with unset cements, the reason for this being that free lime is always liberated in the process of setting. The addition of more lime to the cement of course will increase this action. In this specimen, too, the 10% of lime replaced an equal quantity of cement, and decreased to this degree any possible automatic pore-closing effect from the full hydration of the cement as already described.

"(*f*) That the addition of Sylvester wash was harmful."

The theory of the addition of alum and soap is that they combine and coat the pores with a water-repellant material. It is difficult to see, however, how such an action could occur, and yet the particles of the cement remain uncoated with the same water-repellant material which would prevent their full hydration and the swelling and void-filling action resulting therefrom.

"(*g*) That the addition of clay to the cement had a slightly beneficial result."

It is well known that clay is a colloidal material with respect to water, that is, that it remains suspended in water or holds water in suspension. When mixed with cement, it would seem that this action could not but retard evaporation, and then tend to promote the further hydration of the cement. It is also probable that the clay would have some void-filling effect.

It is affirmed, quite confidently, sometimes, that this disintegration of concrete between high and low water occurs only in northern latitudes, though the writer has never seen any very convincing evidence adduced to substantiate this claim, and that the disruption of concrete is due to the freezing of water in the pores and not to crystallization, neither action can occur, however, without the open pore to pocket the water, and to the open pore must be attributed the primary cause of trouble.

Mr. Larsen's discussion (pages 693-699) reporting his tests on the disintegration of concrete by salt water is interesting in its general confirmation of the results reported by Mr. Bakenhus as to the no-longer-to-be-questioned fact of such disintegration, but it is impossible to pass his final conclusion unchallenged.

He states that his results "confirm in a general way the conclusion of Mr. Bakenhus that * * * integral water-proofing has a detrimental effect on concrete." The writer has studied Mr. Bakenhus' paper very carefully, and fails to find anything either in his conclusions or in a detailed analysis of the tests to indicate even in the remotest way that "integral water-proofing has a detrimental effect on concrete." That paper states very explicitly that integral water-proofing was used only in two specimens (Nos. 22 and 24) and that both of these were lean mixes (1:3:6). In No. 22, 10% of

hydrated lime was "substituted for an equal quantity of cement;" in No. 24, "to each bag of cement there was added 4¾ lb. of clay." Clay is just as properly an integral water-proofing as lime, unless Mr. Larsen confines his definition of integral water-proofing solely to hydrated lime, and, if he does, his failures are easily explained, as will be shown later. Mr. Bakenhus states that No. 24 "came through * * * better than all the other specimens of a similar mixture, save only No. 15 (low alumina cement) and No. 20 (extra well-mixed concrete)." In other words, thirteen specimens of the 1:3:6 mixture were made, and the one to which the integral water-proofing, clay, had been added, ranked third in quality, the two ahead of it being special. Mr. Rhett.

Now, as to No. 22, to which hydrated lime had been added, Mr. Bakenhus states:

"This specimen is also poorer than eight of the other ten similar specimens in series, showing conclusively, so far as one specimen can, the deleterious effects of hydrated lime when used in concrete immersed in sea water."

This finding is entirely in accord with those of other investigators, and entirely in accord with the now generally accepted theory as to the cause of the disintegration of concrete by sea water, but it happens that, primarily, this has nothing to do with the theory of integral water-proofing.

It has been shown* that the lime is the element in the cement which is attacked by the sulphates and chlorides in the sea water, and this fact has been substantiated by other investigators. The addition, then, of more lime could not fail to increase this action, and, in the specific case of Specimen No. 22, the lime added replaced an equal percentage of cement, and this made a leaner mix.

As to Mr. Larsen's own tests, they certainly do not show that "integral water-proofing has a detrimental effect on concrete." Such a statement could only mean either that all integral compounds were the same, or that he had tested all known compounds, and there is certainly nothing shown in his tests to substantiate either claim. As a matter of fact, there are many of these materials on the market. The Bureau of Standards has reported† tests on more than twenty, and the theories on which they are based are radically different.

In fact, the hazy comprehension with which the subject of integral water-proofing continues to be discussed is astonishing, in view of the simplicity of the rational theory on the subject, and seems to have its foundation in a very general lack of knowledge of some of the most important characteristics of the most widely used of engineering materials, namely, Portland cement. Portland cement seems to con-

* *Technologic Paper No. 12*, Bureau of Standards.

† *Technologic Paper No. 3.*

Mr. Rhett. tinue to be regarded as a more or less passive agent, whereas the experiments of Michaelis, Cabolet, the Bureau of Standards, Nathan Johnson, and others have shown, on the contrary, that it contains elements which, though latent under ordinary conditions, are capable, under proper conditions, of a great increase in volume during hydration. The function which this characteristic may be made to play in rendering concrete non-porous seems to be complacently overlooked. It is possible to bring this action into play with a very great void-closing effect, and it is possible, moreover, to reduce the voids by lubrication of the aggregate; and the accomplishment of these two perfectly comprehensible results is the rational theory of integral water-proofing.

The elimination of the pores is acknowledged and has been proved to be the secret of the preservation of concrete subject to salt water tidal influences, and any elimination based on these two simple principles would be, and has been proved to be, just as effective under salt water as elsewhere. There are two conspicuous instances in the vicinity of New York City where integral water-proofing has been used in concrete immersed in salt water, and the concrete has been unaffected. These are Dry Dock No. 4 of the Brooklyn Navy Yard and the pier on Mr. J. P. Morgan's place at Glen Cove, Long Island.

Mr. Brown. MARSHALL W. BROWN,* ASSOC. M. AM. SOC. C. E.— The discussion of this paper has drifted toward the failure of concrete structures, due to the action of sea water. The speaker believes that great attention should be given to the nature of the stone used in the concrete.

If it is assumed that a structure has been adequately designed and properly built to withstand the forces acting on it as a structure, then its life depends mainly on its ability to resist the constant and all-powerful force of sea water acting on it as a destructive agent.

This force is both chemical and mechanical. The chemical reaction, being promoted by the presence of moisture, is facilitated by the mechanical action of the water, which, carrying away particles that have been disintegrated, presents new surfaces to be acted on.

The chemical destruction of any particular mass of concrete is slow. The rate of the mechanical destruction varies greatly, depending on the intensity of the wave action and the nature of the surface on which that action takes place.

The rate at which concrete disintegrates increases with the intensity of the wave action, and with the increasing roughness of the surfaces exposed.

In any volume of concrete there are three materials which are acted on, namely, the cement, the sand, and the stone. As the cement which binds the whole mass together is the one material which is

* New York City.

most readily acted on chemically, its rate of destruction must be reduced to a minimum. This is done in a number of ways: Mr. Brown.

First.—By reducing the quantity of cement needed in a mass, that is, by proportioning the sizes of the sand and stone in such a way that the volume of the voids filled by the cement in the mass is as small as possible.

Second.—By using sand and stone which are in themselves chemically inert and impervious to moisture, and by placing the mixture of these materials in such a manner that the mass, as a whole, when set, is impervious to moisture.

This eliminates all chance of disintegration of the interior of the mass, and confines it to the surface exposed directly to the action of the water. Without moisture, chemical action cannot take place.

The first disintegration of the surface of concrete takes place very slowly, and is mainly chemical. The surface is hard and smooth, and the water has slight effect on it mechanically. Gradually, the cement is eaten away, and a close examination shows that the area of chemical action has been greatly increased around the particles of sand. These are washed away, and, as the action continues, the stone is exposed. After a time, the whole surface, exposed to the action of the water, appears to be one mass of stone surrounded by small seams of mortar composed of sand and cement.

Thus far, only the outer surface of the structure has been displaced, and the integrity of the whole structure thereafter depends mainly on the character of the stone used. On it comes the chemical action of the sea water, the intensive mechanical action of the waves dashing against it, as well as the effect of frost, all tending to loosen and tear each individual particle of stone from the cement which binds it to the structure.

For this reason the speaker believes that the character of the stone has much to do with the life of a concrete structure exposed to the action of sea water. The stone in the concrete should be chemically inert, insoluble, non-absorbent, and should present a surface to which the cement will adhere with the greatest possible strength.

As far as local structures are concerned, this would practically limit such stone to crushed trap rock, granite, or washed quartz gravel.

The speaker has seen many failures of concrete structures in sea water, and in each instance he believes it has been due to the use of shale rock, sandstone, limestone, and other rocks of a sedimentary nature.

ALBERT LARSEN,* ASSOC. M. AM. SOC. C. E. (by letter).—In 1912 the Grand Trunk Railway System reconstructed a portion of the Mr. Larsen.

* Providence, R. I.

Mr. Larsen.

Back Cove Bridge, at Portland, Me., building two rest piers and re-capping the center pier. The center pier, built in 1892, was of granite ashlar, and was in such good condition that it is still used as the center pier, even with the increased loading. During the progress of the construction of the piers in 1912 Mr. Armour, Masonry Engineer, Mr. Durham, of the J. S. Metcalf Company, and the writer investigated the durability of concrete in sea water in order to determine its suitability for the new rest piers. Various concrete structures (including the test piles of the Aberthaw Construction Company), were visited in Boston Harbor, and from these observations it was finally decided to face the rest piers with granite ashlar, backed with concrete. The Grand Trunk Railway System contemplated future work in Portland Harbor, and therefore actual results of concrete placed in sea water were desirable. Ten 12 by 16-in. test piles, 16 ft. long, were made by various water-proofing methods, and immersed in sea water. Six piles were treated with integral water-proofing; two were plain, one of which was cured in the open for 3 months before being immersed; and two were treated with external water-proofing. A 1:2:4 mixture was used, with sand and crushed stone aggregates. The percentage of voids in the sand was 33.

The proportions and different methods of water-proofing for the piles are stated in Table 11.

TABLE 11.

Pile No.	Treatment.	Cubic feet of cement.	Cubic feet of stone.	Cubic feet of sand.	Gallons of water.
1....	Plain (cured in open, 3 months).....	5	20	10	25
2....	Lye and alum (external).....	5	20	10	25
3....	Plain.....	5	20	10	25
4....	Water glass (external).....	5	20	10	25
5....	Water-proof cement ("*A*").....	5	20	10	25
6....	Regular cement plus the water-proofing compound ("*B*").....	5	20	10	25
7....	Regular cement plus the water-proofing compound ("*C*").....	5	20	10	29
8....	Regular cement plus the water-proofing compound ("*D*").....	5	20	10	24
9....	Regular cement plus the water-proofing compound ("*E*").....	5	20	10	23
10....	Regular cement plus the water-proofing compound ("*F*").....	5	20	10	25

Water-proof cement was used in Pile No. 5, and the others contained "Knickerbocker" cement, either alone or in combination with water-proofing compound. A ½-yd. Smith mixer was used; each batch was turned 26 times, and the time was 1½ min. Portland City water was used.

Mr. Larsen.

The following results were obtained with the cement:

	Neat.	Sand.
One-day test	390 lb.	...
Seven-day test	628 "	318 lb.
Twenty-eight-day test	735 "	405 "

The chemical analysis of the cement was as follows:

$Si\ O_2$	23.46
$Fe_2\ O_3$	9.35
$Ca\ O$	61.24
$Mg\ O$	3.59
SO_3	1.60
Loss	0.64

The piles were fastened to the pile trestle adjoining the spur-track leading to the coal pockets, and were made and immersed in the water on the following dates:

	Moulded.	Placed.
No. 1	October 10th, 1912.	January 23d, 1913.
2	" 3d, "	October 23d, 1912.
3	" 10th, "	" 24th, "
4	" 3d, "	" 24th, "
5	" 3d, "	" 18th, "
6	" 10th, "	" 24th, "
7	" 4th, "	" 18th, "
8	" 4th, "	" 18th, "
9	" 4th, "	" 18th, "
10	" 4th, "	" 18th, "

The following is the formula for the Sylvester wash used in Pile No. 2: To 2 gal. of water add 1 lb. of concentrated lye and 5 lb. of alum, and mix until completely dissolved. This is a concentrated stock. When used, 1 pint of stock solution and 10 lb. of cement are mixed with enough water to make a mixture that will lather freely under the brush. Two coats are applied, the first as soon as the forms are removed (the surface must be wet), and the second as soon as the first is dry.

The formula for the water-glass or sodium silicate method of waterproofing (Albert Meyer) is as follows: After the forms are removed, grind with a carborundum stone any projections due to the concrete seeping through the joints between the boards. Keep the surface damp for 2 weeks after placing the concrete. Wash the surface thoroughly and allow it to dry. Mix a solution of 1 part water-glass (sodium silicate) 40° Baumé, with from 4 to 6 parts of water, total 5 to 7 parts, according to the density of the concrete surface treated.

Mr. Larsen.

The denser the surface the weaker should be the solution. Apply the water-glass solution with a brush. After 4 hours and within 24 hours, wash off the surface with clear water. Again allow the surface to dry. When dry apply another coat of water-glass solution. After 4 hours and within 24 hours, again wash off the surface with clear water and allow to dry. Repeat this process for three or four coats, which should be sufficient to close the pores.

The water-glass which penetrates the pores comes in contact with the alkalies in the cement and concrete, and forms an insoluble hard material, causing the surface to become very hard to a depth of $\frac{1}{8}$ to $\frac{1}{2}$ in. according to the density of the concrete. The excess of sodium silicate which remains on the surface, not having come in contact with the alkalies, is soluble, and is easily washed off with water. The reason for washing off the surface between each coat and allowing the surface to dry is to obtain a more thorough penetration of the sodium silicate.

The tops of the concrete piers were treated by the water-glass method, and when examined on March 13th, 1917, were found to be in as good condition as when treated. The tops were finished with a 1:2 mortar with granite chips.

The piles were examined by the writer on March 13th, 1917, and photographs then taken are reproduced as Figs. 2 and 3.

The fungous growth was not removed from the piles.

The following indicates the condition of the piles:

No. 1 pile: Perfect condition.
No. 3 " : " "
No. 4 " : Nearly perfect condition.
No. 2 " : " " "
No. 5 " : Very marked deterioration at base of pile.
No. 7 " : " " " from low to high tide.
No. 9 " : " " " " " " " "
No. 6 " : Very decided deterioration from low to high tide; very bad condition.
No. 8 " : Very decided deterioration from low to high tide; very bad condition.
No. 10 " : Very decided deterioration from low to high tide; very bad condition.

The results are very interesting, and confirm in a general way the conclusion of Mr. Bakenhus that a 1:2:4 is better than a leaner mixture; that external water-proofing does not help when the concrete has been made as dense as possible; and that integral water-proofing has a detrimental effect on concrete.

From the writer's observations he would say that, once the concrete is affected by the action of the sea water, the rapidity of the disin-

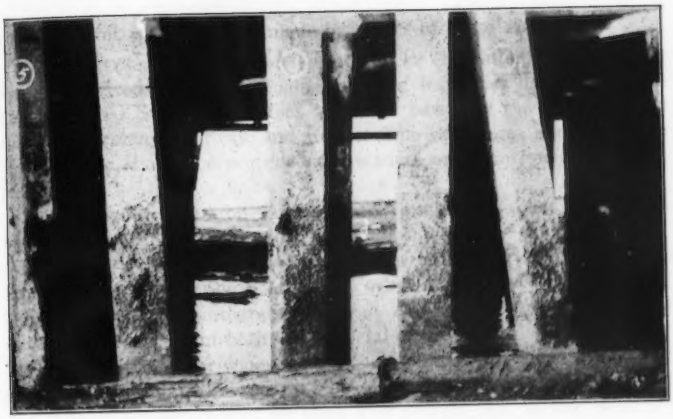

FIG. 2.—SPECIMEN PILES TESTED IN SEA WATER.

FIG. 3.—SPECIMEN PILES TESTED IN SEA WATER.

tegration is increased, as the water gets in between the stones and the mortar faster and thus breaks up the concrete. The writer thinks this may be overcome by facing the concrete with a dense mortar to a depth of from 1½ to 2 in. This may be done during the process of building, or afterward by the cement gun. It would be interesting to experiment with concrete made by either of these methods. Mr. Larsen.

W. WATTERS PAGON,* M. AM. SOC. C. E. (by letter).—The author has summarized the most valuable series of tests that have been made in the United States; tests that are on a par with the several series made in Germany, Norway, and Russia some years ago; and the writer feels that he should be accorded the sincere appreciation of the Profession. Mr. Pagon.

The destructive action of sea water on concrete has become in recent years a very serious subject in all those cities on the Atlantic Coast north of New York City, and in corresponding climatic regions on other sea coasts. South of New York City, the writer is aware of only two cases of disintegration, one at Atlantic City† and the other in Chesapeake Bay, but both were special cases.

The writer's experience in a specific case on the Connecticut shore of Long Island Sound may be of interest, and is quoted briefly here from a paper written by him, and now on file in the Society's Library. The concrete which suffered from the sea-water action consisted of the copings of a series of bridge piers which were faced with granite masonry below the coping. The facing extended up to mean high tide, but the copings, which extended from this point (Elevation 0) to Elevation + 1.5, were of 1:2:4 concrete without facing.

Pier No. 4, which suffered most severely, was constructed on December 19th, 1913, during weather sufficiently cold to require the use of steam to warm the mixing water. After placing, the concrete was covered with a tarpaulin, stretched from one side of the cofferdam to the other, and cold steam was allowed to escape beneath this. During the week of January 19th to 24th, 1914, there was considerable freezing weather, accompanied by high tides. The result was the formation of a thick ice coating over the concrete surfaces. When this had melted, on January 26th, it was found that the surface of Pier No. 4 had been loosened, and large pieces of scale could be removed. Within a week the mortar between the stones of the gravel had disintegrated and fallen out, leaving the stones projecting. The loose portions were removed with a hammer, and behind them the concrete was perfectly sound. At the end of two weeks, the ice

* Baltimore, Md.

† "Report on the Destructive Action of Sea Water on Concrete", reprinted from the *Monthly Journal* of The Engineers' Club of Baltimore.

Mr. Pagon.

coating formed again, and when this had disappeared the erosion was found to have increased greatly.

The concrete used throughout the work was of a wet "sloppy" consistency. The forms were tight, so that there were no pockets. Immediately after removing the forms, the surfaces were rubbed with carborundum blocks. Cow Bay sand was used, and a mechanical analysis showed it to be too fine; there was also some clay. Analysis of the cement showed it to be excellent. Later, a coarser sand was used, with the results described hereinafter.

In the paper quoted, the writer discussed in detail the various possible causes of this disintegration, and he refers interested readers thereto. He felt that undoubtedly the fineness of the sand was one of the factors causing disintegration, and, therefore, drew up a specification for the sand which was used in all later work, under which, for acceptance, not more than 70% should pass the No. 20 sieve. Long Island sand testing as low as 40% could be obtained from one dealer, but it was found that sand which tested below 60% was too coarse for reinforced concrete work, where a smooth, easy flowing concrete is necessary. To avoid delay in obtaining sand, 70% was adopted as a criterion, and immediately a noticeable change in the strength of the concrete was shown in all the field tests, in the time of setting of the concrete, and also by observation of the concrete itself.

In the writer's opinion, however, the sand was by no means the governing factor. From the detailed description which is given in the paper quoted, it will be seen that the first failure of the surface skin on the concrete always took place where a pebble of the gravel aggregate was close to the surface, and where, therefore, the surface skin had small adhesion to the backing. After this area of skin had peeled off, it was a simple matter for the water, working its way along the surface of the pebble, to force off (by freezing) the surface skin between pebbles. When the skin was gone, the porosity of the concrete, due to the fineness of the sand, caused the disintegration of this mortar, as previously described. Photographs of the concrete just after the beginning of disintegration revealed innumerable little "pock-marks" where the pebbles showed through the broken skin.

In order to test this theory, three specimens were made for the writer by the contractors, McHarg-Barton Company. These were 4 by 4-in. by 10 ft., reinforced axially with a $\frac{3}{8}$-in. round bar, hooked at the upper end. The mixtures were as follows:

Specimen	No. 1	1:2:0
"	No. 2	1:2:4
"	No. 3	1:1½:3

These were removed from the forms in 24 hours (in order to simulate as nearly as possible the temperature and greenness conditions of

FIG. 4.—PIER NO. 3, MARCH 13TH, 1917. EARLY STAGES, SHOWING PITTING.

FIG. 5.—PIER NO. 4, FEBRUARY 3D, 1914. SCALE GONE; CONCRETE PITTED, SHOWING STONES OF GRAVEL.

FIG. 6.—PIER NO. 4, FEBRUARY 5TH, 1914. SURFACE SCALE LOOSENED AND FALLING OFF, EDGES ROUNDED OFF BY DISINTEGRATION.

FIG. 7.—PIER NO. 4, APRIL 4TH, 1917. DAMAGED CONCRETE REMOVED; REINFORCEMENT PLACED, READY FOR APPLYING NEW MORTAR FACING.

the pier coping). No. 2 was cracked in handling in one place; No. 3 in three places. When 3 days old the specimens were hung in the river so as to extend above high tide and below low tide. Mr. Pagon.

After the first tide, they were all covered with a white coating, except on the troweled face. At the end of 5 weeks, while they were being shifted to another place, they were accidentally lost. No. 1, however, was in perfect condition; Nos. 2 and 3 were rather badly eaten away, especially at the cracks, where, in fact, No. 2 was eaten away so completely as to expose the rod.

The theory having proved satisfactory, so far as the test went, it was decided to cut away the face of the coping and replace it with 1:2 mortar made of sand bought under the new specification. This was done on April 4th, 1914, the mortar being mixed to such a consistency that it could be poured and stirred like thick cream. The forms were left on for a couple of weeks to protect the concrete from the sea water as far as possible. When they were removed, the mortar was in good condition, although there were numerous instances of bubbles having formed while it was being handled and placed. The surface was not rubbed for fear of causing injury to the protecting skin.

When examined 2 years later, this mortar facing was in perfect condition, although it had passed through two winters. This would seem to confirm the theory, in so far as one test can confirm it.

If other members of the Society have had similar experiences, it would certainly be valuable to hear from them, and the writer's only regret has been that in the Aberthaw tests, described by Mr. Bakenhus, none of the specimens was of mortar only. The writer feels strongly that the relatively good condition of the 1:1:2 specimens is due not only to the greater percentage of cement to aggregate, but also to the greater percentage of cement and sand combined to stone, or, in other words, that a 1:1:2 mixture approaches more nearly to a mortar.

R. J. Wig* and Lewis R. Ferguson,† Assoc. Members, Am. Soc. C. E. (by letter).—The increasing necessity for marine structures, due largely to the improvement of harbor facilities and the military work along our sea coasts, gives an added value at the present time to the paper presented by Mr. Bakenhus. Messrs. Wig and Ferguson.

The points he brings out are largely confirmed by an extensive investigation recently completed by the writers. During this investigation practically all the concrete structures along the Pacific, Atlantic, and Gulf Coasts, as well as a number in Canada and Cuba, were carefully examined. Their present condition was noted, and in most

* Washington, D. C.
† Philadelphia, Pa.

Messrs. Wig and Ferguson.

cases a detailed description of the materials and methods used in construction were obtained.

The effect of the quantity of water used in mixing the concrete is rightly emphasized by Mr. Bakenhus, for this factor undoubtedly has a most important bearing on the ability of the structure to resist sea-water action. He states that the specimens made of wet or very wet mixtures are in much better condition than those made of dry concrete, and this is substantiated by the data he presents.

Perhaps it would have been better if the terms "wet" and "very wet" had not been chosen for describing the consistencies used. Ordinarily, in present practice, concrete which would be designated as "wet" or "very wet", contains a great deal more water than was used in any of the mixtures from which the specimens were made. Even in the very wet mixtures, the notes in Table 3-*A* indicate that the concrete was tamped. In ordinary practice, very wet or even wet concrete would flow into place, and it would be so soft that tamping would not be necessary, nor could it be compacted in this manner. The writers believe, as a result of their investigation previously referred to, that, with concrete subjected to sea-water action, the best results are invariably obtained when a consistency is used which will permit of light tamping. This light tamping should produce quaking in the mass. If the concrete is mixed too dry, a porous condition will result; and if too much water is used in mixing, a lack of density, together with a chalky condition of the surface, results. In both cases, the concrete is very susceptible to disintegration by sea-water action. For reinforced work, as usually constructed, a slightly wetter mixture is required than what the writers believe to be the best consistency, owing to the necessity of thoroughly embedding the reinforcement.

It is possible, however, that some method may be devised of placing the concrete for reinforced work so that the ideal consistency can be used and, at the same time, secure thorough protection of the embedded steel. The ideal consistency is that which produces concrete of maximum density.

The author indicates that great care was exercised in proportioning the aggregates and in mixing the concrete, the time of mixing, after all the ingredients were placed in the drum, being about 2 min. This undoubtedly had a very beneficial effect on the concrete.

In many of the structures examined by the writers the deterioration in evidence, at least in part, can be attributed to a lack of care in preparing the concrete. More care must be taken in the mixing of the concrete than has too often been the case in the past, if more successful results are to be secured with concrete structures in sea water. In fact, far more care must be taken in every operation connected with constructing concrete which will be subjected to sea-water action than is necessary for land structures.

Messrs. Wig and Ferguson.

Only by giving strict attention to minute details, which in land structures would be trivial, can satisfactory results be obtained. Minor defects, which ordinarily would be unimportant, are often the starting points of deterioration which ultimately spreads to sound parts of the structures and cause failure when sea-water action is to be resisted.

Although the information which Mr. Bakenhus presents is of great value for the locality of Boston, care must be taken in drawing too general conclusions from it. There is a great difference in the action of sea water on concrete in different localities due to climatic conditions as well as varying physical actions, such as wave action and abrasion from floating débris and ice.

The saline content of the water also has a marked effect. The undiluted sea water along our coasts does not vary greatly in the quantity of salt contained, but, where structures are near the mouths of rivers, the sea water is frequently diluted to a considerable extent.

The writers believe that few very general statements can be made on the subject of the effect of sea-water action on concrete, but the peculiarities of each individual locality must be studied before attempting to state the methods to be followed, which will insure permanent concrete structures.

Mr. Bakenhus.

R. E. BAKENHUS,* M. AM. SOC. C. E. (by letter).—The writer has read with interest the various discussions of his paper. Information is offered tending to confirm the results of the Boston tests. The opinion advanced by Mr. Yates that, in setting, a surface is formed on concrete, which will resist successfully the action of sea water on cement, is significant. If a surface coat protects the concrete from the chemical action by sea water, then it becomes very important to know the character of this protective surface, to encourage or bring about its formation, and to protect it from mechanical injury. Mr. Yates cites examples of bridge piers in fresh water showing no deterioration from freezing and thawing and no chemical action, though mechanical injury to the surface exists. This tends to bear out the theory that it is the chemical reaction between the sea water and the concrete that is responsible for most of the deterioration of the latter.

A number of causes are undoubtedly contributory to the deterioration of concrete in tidal sea water. It depends first on the destructive agents existing in the sea water and the atmosphere, and second on the materials of which the concrete is made and the manner in which they are combined. The active possible destructive forces may be listed as follows:

(*a*).—Mechanical injury by floating objects or débris;

(*b*).—Mechanical injury by water, waves, and currents;

(*c*).—Mechanical injury by wind action;

* Washington, D. C.

Mr. Bakenhus.

(*d*).—Mechanical injury from freezing and thawing;
(*e*).—Chemical reactions between the sea water and cement;
(*f*).—Chemical reactions between the sea water and the sand or stone of the concrete;
(*g*).—Physico-chemical reactions of the sea water and the concrete, such as the solution of elements of the concrete in sea water, or the formation and deposit, in the pores of the concrete, of crystals occupying greater volume than the original materials, accompanied by minute internal stresses;
(*h*).—A combination of any or all of these destructive effects.

The elements tending to resist destruction may be listed as follows:

(*a*).—Density of the concrete, that is, reduction of pores to a minimum, accompanied by increased resistance to internal stresses;
(*b*).—Thorough mixture of the ingredients, so as to give a uniform composition of the mass;
(*c*).—Freedom from accidental defects, which may act as starting points of deterioration;
(*d*).—Chemical and physical characteristics of the cement, sand, and stone, making these materials neutral in the tidal range of sea water;
(*e*).—Strengthening of the concrete by a high proportion of cement;
(*f*).—Formation of a protective coat, which is inert in the tidal range of sea water and which, unless mechanically broken, prevents chemical action.

Deterioration is the result of the interaction of the various destructive forces and the resisting elements. In the tests which have been described, the effort was made, by comparing parallel series of specimens, to single out and test the variable elements in the concrete itself, one at a time. The destructive elements of the sea and air might have been similarly segregated, and, in addition, the tests might have been repeated in various climates and in fresh water, as well as in salt water, so that the effect of mechanical injury from floating débris, the effect of wave action, the effect of freezing, the effect of climate and of moisture and air, and, finally, the effect of the chemical and physico-chemical action of the sea water might have been independently determined. In part, this is accomplished by the specimens extending below low tide and above high tide. In the absence of any more elaborate series of tests, the experiences with actual structures in many localities may supplement the data already available, and

Mr. Bakenhus.

enable engineers to reach definite conclusions. The writer, therefore, looks forward with interest to the report of the extensive investigations made by Messrs. R. J. Wig and Lewis R. Ferguson, for the Bureau of Standards, in all parts of the country.

In tidal sea water at Boston, the destructive effects, as shown by the tests, occur where the concrete is alternately exposed to the sea water and the air. Exposure to either the sea water or the air alone did not bring about deterioration. This would indicate that it is not simple chemical reactions between sea water and cement that bring about destruction of the concrete, as these could go on below tide level as well, but that the reactions are dependent on air as well as on water, and are most probably of a physico-chemical nature.

The effect of integral water-proofing on the durability of concrete in sea water is discussed by Messrs. Larsen and Rhett. The very interesting tests for the Grand Trunk Railway, at Portland, Me., referred to by Mr. Larsen, agree with the Boston tests in showing that concrete can be made without so-called integral water-proofing and remain in sea water for several years in perfect condition.

Two of Mr. Larsen's specimens, treated with external water-proofing, did not fare so well as the plain concrete; and six, made with cement, combined with various water-proofing compounds, are stated by him to show very marked deterioration.

Three of the Boston specimens were mixed with materials of the so-called integral water-proofing type. No. 22 had a mixture of 1 part of hydrated lime and 9 parts of cement. No. 23 was mixed with Sylvester wash, made as follows:

(*a*).—Bar soap, light colored, dissolved in water, 1¼ lb. of soap to 15 gal. of water;
(*b*).—Powdered alum, 3 lb., mixed with each bag of cement;
(*c*).—Materials of concrete mixed dry;
(*d*).—Hot soap solution dumped into a barrel of cold water, and used to mix the material to the proper consistency.

No. 24 contained pulverized clay in the proportions of 1 part of cement, $\frac{1}{20}$ part of pulverized clay, 3 parts of sand, and 6 parts of stone.

The clay specimen fared very well, but this is not true of the specimens containing hydrated lime and Sylvester wash.

The Boston tests are not sufficiently extensive as to the use of integral water-proofing to warrant drawing any general conclusions, and it cannot be stated, as a general principle, that they, in themselves, showed that integral water-proofing has a detrimental effect on concrete. Mr. Larsen's tests were more complete on this point, and show consistent results. The Boston tests do not include the

Mr. Bakenhus.

use of external water-proofing, such as was used in two of Mr. Larsen's tests.

Although most of the data available from these two series of tests are not favorable to the use of integral water-proofing, it may be possible, nevertheless, to discover a compound which would improve the durability of concrete in sea water. Very complete tests under service conditions will be necessary to determine finally whether a helpful integral water-proofing can be found.

It is shown by the tests that certain concretes are not stable in sea water at tide levels. Other concretes are stable in the presence of the forces, chemical and physical, that are active in sea water at tide levels. The dividing line between the two classes is not sharply marked. Knowledge of the action and effect of these forces is just as important to the engineer in designing successful concrete structures in sea water, as knowledge of earth pressure, hydrostatic pressure, or other loads. A very considerable volume of empirical knowledge is now available for the engineer from these tests and from other sources. Under existing conditions, it is apparent that concrete structures in sea water should be planned with care, and only by those who have special knowledge of the subject.

Paper No. 1394

AN AERIAL TRAMWAY FOR THE SALINE VALLEY SALT COMPANY, INYO COUNTY, CALIFORNIA*

By F. C. Carstarphen, Assoc. M. Am. Soc. C. E.†

With Discussion by Messrs. Richard Lamb, H. F. Scholtz, and F. C. Carstarphen.

Synopsis.

This paper gives a brief statement of the prominent features of the location, construction, and operation of an aerial tramway built to carry salt, at the rate of 20 tons per hour, a distance of 13½ miles, from Saline Valley, over the Inyo Mountains, to a point in Owens Valley, California.

It is assumed that the reader is familiar with the terminology of aerial tramway design; also, that the ability of an aerial tramway system to transport materials economically and efficiently at the rate of 250 tons per hour or less is so well known as to make extensive discussion of these points unnecessary.

California now possesses one of the most novel aerial tramways ever constructed. This was built over the Inyo Mountains for the Saline Valley Salt Company, of Los Angeles, Cal.

In 1904 Adolf Bleichert and Company completed for the Argentine Republic, a tramway, 22 miles in length, with a difference in terminal

* Presented at the meeting of May 2d, 1917.
† Now M. Am. Soc. C. E.

elevations of 11 500 ft., thereby establishing a record for length of lines operated continuously and successfully. In 1915 the American Steel and Wire Company completed an aerial tramway for the Spring Canyon Coal Company, of Storrs, Utah, which carries 285 tons of coal per hour.

Although these two structures exceed the Saline Valley tramway in length and capacity, respectively, neither of them crosses a mountain range, nor does either show such boldness of engineering design. The engineers who undertook the construction of this tramway were fitted by experience to solve the many problems which confronted them. As early as 1895 the Trenton Iron Company designed a tramway, 12 miles long, for the Compagnie Haitienne, of Port de Paix, Haiti, and it has been maintained in successful operation ever since.

The purpose of the Saline Valley Salt Company, in building this aerial tramway, was to transport salt from Saline Valley, over the Inyo Mountains, to the railroad in Owens Valley. The tramway is in Inyo County which is remarkable as possessing the highest and lowest spots in the United States. Mt. Whitney, elevation 14 501 ft., is the crowning height of the Sierra Nevada Mountains, forming the west wall of Owens Valley; Death Valley, to the east, has an elevation of minus 280 ft., and is the lowest spot in the desert. An observer standing on the summit of Telescope Peak of the Panamint Range can view the extremes in elevation of the Republic.

It may be remarked in passing that Owens Valley, elevation approximately 3 600 ft., possesses a river of such magnitude that the City of Los Angeles has built an aqueduct, 274 miles long, for the purpose of making this mountain stream available for the domestic water supply of the city. The Owens River flows into Owens Lake, which is a dead sea, without outlet. The waters of this lake are sufficiently rich in sodium carbonate to make its extraction profitable. At present, plants on the east side of the lake are producing soda ash and sodium bicarbonate in large quantities.

To the east, beyond the Inyo Mountains, is Saline Valley, with an elevation of 1 100 ft. This valley has no water system, but is remarkable for several large springs, and there is flowing water in Hunter Canyon. To the east of Saline Valley lies the romantic Death Valley, its depressed floor dotted with borax deposits. Thus, it may be noted, the commercial worth of these valleys varies with altitude. The tempera-

ture of the summer air of Owens Valley is not excessive, but Saline and Death Valleys are no doubt quite the hottest places that can be found on earth. Temperatures of 120° Fahr. in the shade prevail for considerable periods, and only because of the absence of humidity can the summer heat be endured.

The topography of Inyo County owes its extreme boldness to the simple nature of the faulting, which is responsible for the Sierra Nevada and Inyo Mountains. When the great blocks of the earth's crust were thrust upward they assumed a tilt toward the west, so that the slopes on that side are gradual; the east fault plane has been carved into bold escarpments of exceeding grandeur. The elevations of the floors of the valleys between the successive mountain ranges indicate the relative power of the faulting forces. At the time of this great displacement of the earth's crust, titanic agencies were at work, and in regions of ancient volcanic activity deposits of precious ores are often found. This district is not an exception. In the early Eighties a gold stampede took place into the Saline Valley and the Ubehebe Mountains forming its eastern boundary. It is said that more than 2 000 people were camped in this valley during the height of the excitement. At that time it became generally known that there was a great salt deposit of remarkable purity in Saline Valley. A view of this deposit from the flanking mountains on the west is most impressive. The most important portion of the salt flat covers an area of approximately 1 500 acres, and the purity of the salt is enhanced by a natural refining process which is in constant operation, due to the remarkable fact that there is a series of large springs on the western rim of the salt flat, the water of which inundates the salt beds during the winter, and yields to the excessive evaporation induced by the summer heat. The retreat of the water deposits the pure salt crystals, which form when the brine reaches the point of saturation.

The salt claims located at that time have always been assumed to possess great value, provided transportation facilities could be obtained to ship the salt to the various markets.

Surveys had demonstrated the impracticability of building a railroad into the valley; the mountain barrier was so great that the cost of constructing such a line was excessive. Two methods of transportation were then considered. The first was by a pipe line over the Inyo Range, through which the brine formed on the salt flat could be

pumped to evaporating vats adjoining the railroad at Owens Valley. This project was examined very carefully, and estimates of cost were prepared, but it was found that although it was feasible for the transportation of brine, it did not afford a means of bringing in the supplies needed by the operations incidental to pumping. Accordingly, the merits of an aerial tramway were discussed, and, in order to ascertain the cost, and determine a suitable location for such a tramway, a survey was begun in April, 1911, under the direction of W. H. Leffingwell, M. Am. Soc. C. E. Several trial lines were run, and a location was selected in the latter part of May. Under the direction of Mr. C. H. Wickham, Field Engineer for the Trenton Iron Company, a final location was completed in July. The profile, together with the topographical surveys, were submitted to the Trenton Iron Company for consideration. An estimate was prepared, and the final contract was signed on August 14th, 1911, between The Trenton Iron Company, a subsidiary of the American Steel and Wire Company, and the Saline Valley Salt Company, a corporation of the State of Arizona.

This contract called for the preparation of the designs and finished drawings, as well as the wire cables, carriers, and machinery, for a Trenton-Bleichert tramway to carry salt weighing 60 lb. per cu. ft., the slope length of the line being 69 645 ft., the capacity 20 tons per hour, the elevation of the discharge terminal above the loading terminal, 2 450 ft., the carriers to have a volume of 12 cu. ft., and the speed of the traction rope to be 500 ft. per min. This resulted in a spacing of 525 ft., or 63 seconds, between contiguous carriers. More than 112 h. p. were required for its operation. The following items occur as prominent parts of the specifications:

Patent locked coil steel track cable, $1\frac{1}{4}$-in.....	13 850 ft.
" " " " " " $1\frac{1}{8}$-in.....	55 450 "
" " " " " " $\frac{7}{8}$-in.....	69 300 "
Special steel traction rope, $\frac{3}{4}$-in.....	141 000 "
Special steel buckets, capacity 12 cu. ft., with protecting covers; and hangers, carriages, and patent compression grips.....	286
Intermediate supports.....	120
Track cable saddles.....	240
Steel traction rope rollers, with shafts, bearings, bolts, washers, foot castings, etc.....	240

The specifications also included the supervision of the erection of the timber work and attaching the machinery; the equipment for one loading terminal, one discharge terminal, five intermediate control stations, twenty-one rail structures, twelve anchorage-tension structures, and one double-tension structure; tools for coupling and splicing track cables and traction rope; the necessary signal gongs for the control of the line when in operation; track cable oiling cars, traction rope oiling tanks, and water carriers.

The difficulties of construction on this line may be inferred from an inspection of the profile, Fig. 1. Aerial tramways have been built in the past so that the line traversed country possessing exceedingly rough topography, but each has been distinguished by the fact that it has been on the flank of a mountain range, instead of crossing it. It was desirable to find the shortest route between the salt fields and the railroad. The west side of the Inyo Mountains, though broken into a number of precipitous ridges, does not impose extreme difficulties to aerial tramway erection. The average elevation of the crest of these mountains is 10 000 ft. above sea level, and it runs in a northerly and southerly direction. However, there is a saddle in the crest line with an elevation of 8 500 ft., so that it was desirable to have the tramway pass through this gap. By utilizing the difference in elevation between the terminal stations, it was found that the 7 500 ft. required to pass the summit could be obtained by dividing the difference in altitude between the floor of Saline Valley and the summit into three 2 500-ft. sections; also, that the descent from the summit to Owens Lake could be made in two 2 500-ft. sections. The selection of a constant difference in the height of the several control stations was an important factor in deciding on a constant size of traction rope for all the sections. The use of intermediate control and driving stations added flexibility to the location of the line, as any reasonable horizontal angle can be made at such points.

The final location of the line is shown on the map, Fig. 2. It starts from the edge of the salt field, at an elevation of 1 060 ft. and runs south along the mesa for 2¾ miles to the foot of the eastern face of the mountains, which has an elevation of about 1 800 ft. The line ascends abruptly to Station 177 + 50, which has an elevation of 3 720 ft., where Control Station No. 1 is placed. The portion of the line from the loading terminal to Control Station No. 1 is designated

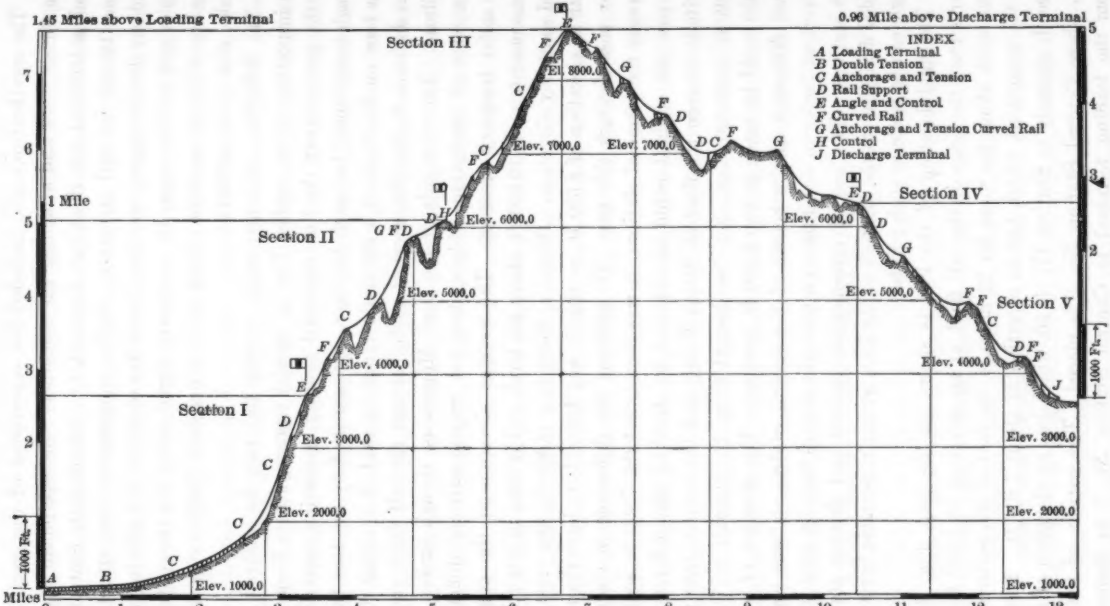

FIG. 1.—PROFILE, AERIAL TRAMWAY, SALINE VALLEY SALT COMPANY, TRAMWAY, CAL.

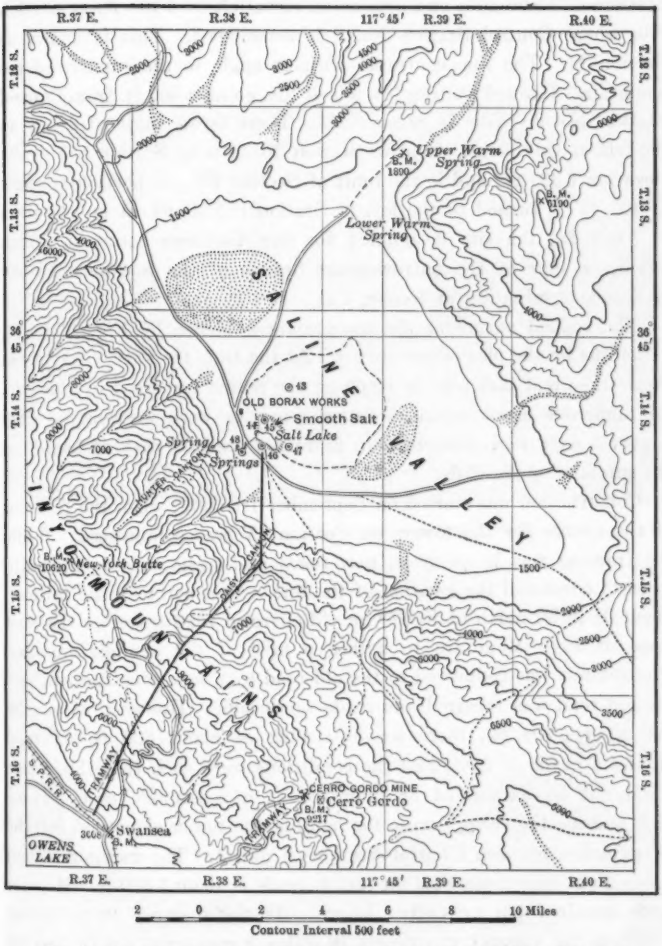

FIG. 2.—LOCATION OF AERIAL TRAMWAY OF SALINE VALLEY SALT COMPANY (U. S. G. S. TOPOGRAPHY).

Section I. A horizontal angle of 35° 30′ is turned to the right, or westward, at this control station. The line crosses Daisy Canyon between Stations 223 and 244, and attains an elevation of 6 100 ft. at Station 270, where Control Station No. 2 is established. This is known as Section II. The line continues without angle to the summit of the mountain. Control Station No. 3 is at this point, 8 300 ft. from Control Station No. 2. This is Section III. There is an angle of 2° 28′ to the left at this point. Control Station No. 4 is at Station 550 + 66, elevation 6 330 ft., and is the limit of Section IV. A horizontal angle of 10° 48′ is turned to the left to Station 685 + 63, at an elevation of 3 625 ft., the site designated for the discharge terminal, which adjoins a spur of the narrow-gauge branch of the Southern Pacific Railroad, terminating at Keeler, Cal.

The rugged nature of the topography is shown by Figs. 3 to 14, as well as by the plat of the survey. At the time the survey was made there was great difficulty in reaching the points traversed by the line. In numerous cases, when the survey parties were working in deep canyons, days were consumed in finding a feasible path of ascent to the summits of the cliffs.

Construction was started on September 1st, 1911, when the framing of the timber for the towers on Section IV was commenced. While the framing was in progress, new roads and trails were being built, so as to command the location of the line. At a point on the railroad about 3½ miles north of Keeler an old charcoal road traverses the west slope of Inyo Mountain to within a mile of the summit crossing. The summit was connected to the old road by a new construction, and the old road was repaired and made serviceable. However, at an elevation of 5 900 ft., there was a stretch of about 330 ft. of road having a grade of 25%, and the conditions were such that this grade could not be eliminated or improved at a reasonable cost. Thus, 25% became the ruling grade for hauling the material needed for the construction between Control Stations 4 and 1. The maximum load which eight horses can haul on such a grade is about 5 000 lb. Heavier loads required ten or twelve horses. As the distance from Owens Valley to the summit was nearly 10 miles, a camp was established on the road about 3½ miles west of the summit. By this arrangement teams could make one trip per day from the railroad to the camp, leaving their loaded wagons for other teams, quartered at the camp,

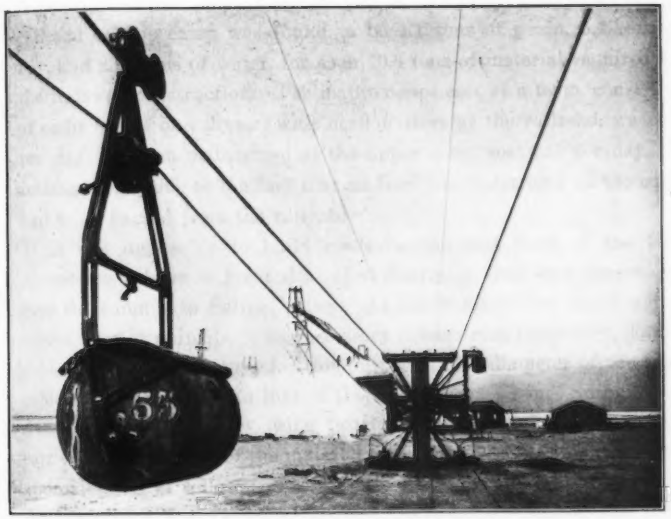

FIG. 5.—BUCKET LEAVING LOADING TERMINAL.

FIG. 6.—LOADED AND EMPTY CARRIERS PASSING ON 80% GRADE, SHOWING VERTICAL POSITION MAINTAINED BY BOTH.

to haul to the summit and unload. The camp teams could make three trips in 2 days. The total weight of material hauled from the railroad to this camp was found to be 1.1 tons of grain, 5.4 tons of hay, and 23.2 tons of water, for each 70.3 tons of material required for the tramway construction. The maintenance cost of a team, consisting of eight horses and driver, with headquarters at the railroad, was $15 per day. A team maintained at the upper camp cost $21 per day, the increase being due to the fact that all feed and water used at the camp had to be hauled from the railroad.

It was impossible to build roads on the east flank of the Inyo Mountains. After a great deal of difficulty, a trail was constructed over the summit to Saline Valley. As heavy machinery could not be moved by pack animals, it was necessary to construct temporary, double-cable, reversible tramways for this purpose. The diameter of the track cables used was ¾ in. and that of the traction rope, ⅜ in. Suitable carriers were improvised by using two or more standard tramway timber carriers. The weight of the material transported by these jigbacks was approximately as follows: From Control Station No. 3 at the summit, for Structures Nos. 19, 18, 17, 16, and the towers in Section III, about 60 tons, at a cost of from $2 to $4 per ton, the difference being accounted for by the fact that the material was unloaded from the line as required: From Structures Nos. 20 to 15, a distance of 8 300 ft., 600 tons were moved, at a cost of $4.20 per ton; from Structures 15 to 11, 2 600 ft. distance, 375 tons at $2 per ton; Structures 11 to 9, 4 000 ft., 260 tons at $3.50 per ton; Structures 9 to 7, 2 700 ft., 210 tons at $2.90 per ton.

The cost per day for the crew required to operate, load, and unload these temporary cableways was from $35 to $42. The capacity of these lines, in tons per day, when operating, may be summarized as follows: From Structures 20 to 15, 13.3 tons; 15 to 11, 33.3 tons; 11 to 9, 23.8 tons; 9 to 7, 29.7 tons. If the capacity is stated in tons per day, including the time of putting up, taking down, and moving the jigbacks, the figures are as follows: Structures 20 to 15, 6.3 tons; 15 to 11, 19.3 tons; 11 to 9, 11.3 tons; 9 to 7, 14 tons.

From Chuckwalla Hollow, between Structures 4 and 5, a line was built to Control Station No. 1. It cost $35 a day for the crew, and took 6 days to build. One trip per day could be handled with this line,

at an average cost of $50. If the material was light, such as wood, water, etc., two trips could be made. This meant a labor cost of more than $25 per ton for handling motors and other heavy pieces of machinery from Structures 4 to 7. This expense is accounted for when it is recalled that the vertical lift is 1 900 ft. in a horizontal distance of 3 500 ft.

Saline Valley can be reached by a wagon road, approximately 55 miles long, which leaves the railroad at Big Pine. About 375 tons were hauled over this road at a cost of $35 per ton. All the cables required between Stations 1 and 2, together with the 75-h.p. motor, transformers, and heavy station material, were moved from the summit to a point in Daisy Canyon about 1 500 ft. west of Control Station No. 2. This material was transported on what is called a "go devil." This device consisted of a timber frame supported on an axle 8 ft. long which passed through two heavy wheels. The rear end of the frame rested on the ground, and was shod with iron in order to prevent excessive wear. On each side of the frame, near the rear end, steel hooks were arranged, so that two men, one on each side of the frame, could lift it free from the road when the gradient was light. On the other hand, these hooks were used to check the velocity of the device when traveling over ground that was soft enough for them to penetrate. The operators used both hooks in coming down steep places, and also assisted the team in steering the device. Fortunately, no road was required for the operation of this machine, as the canyon was fairly straight and the bottom free from ledge rock.

The material was moved to Control Station No. 2 on a tramway constructed with two carrying cables mounting four carriers. A different system was adopted for stringing the cables from the summit to Control Station No. 2, and also from No. 2 to No. 1. This consisted of coupling cables together and letting them down the mountain side by gravity. It was necessary to keep from three to five men at the leading end so as to put the cables on the traction rope guide sheaves of the towers and stations. The velocity of the cable was controlled with 4 by 8-in. blocks bolted together, so that the cable could be squeezed as it passed along. Each one of these extemporaneous brakes would resist a pull of about 1 000 lb. until a groove equal to the depth of the cable was worn in it. When this occurred the clamp was changed so

that the cable would bear on a new spot. From Structure 4 to Control Station No. 1 the cables were pulled up with a winch driven by a gasoline engine. On Sections IV and V the cables were strung and placed under tension in the usual manner, except that on Section V the grade was sufficient to make it desirable to use the gravity method. In placing the traction rope for Sections III and II, it was threaded around the grip sheave at the summit station. The grip sheave acted as a driving sheave, due to the use of a brake on the reel, which imposed tension in the traction rope before it passed around the grip sheave. The traction rope was also passed through hauling clamps before reaching the grip sheave so as to hold it when splices were being made, or in cases of emergency. After getting the traction rope for one side to Control Station No. 1, the upper end at Station 20 was snubbed, and the rope for the opposite side was let down in the same manner. After the upper ends had been spliced, the ropes were cut at Control Station No. 2 and passed around the tension and grip sheaves of this station.

The towers and structures are carried on concrete foundations, and the water required for making the concrete was hauled in tanks or packed by mules for distances ranging from 1 to 7 miles. This was also true for the water required for the camps, except those at the railroad, in Daisy Canyon, and Saline Valley. All permanent camps on the east slope were at elevations lower than 6 000 ft., and those on the west slope lower than 7 500 ft., so as to be below the usual snow line. As the mountains are extremely barren, firewood had to be hauled or packed to the camps from the most convenient points, and these were often at considerable distances.

From October 1st to April snow storms are of frequent occurrence, and, owing to the steepness of the hillsides, constitute a menace to construction at all altitudes above 6 500 ft. In the spring occasional slides have occurred on the eastern slope, and have proved disastrous to the construction crews. The drifting snow was very objectionable, owing to the difficulty of keeping the trails open. Due to these several causes, the work was arranged so that it could be performed at elevations below the snow line during the winter.

The erection of the line was pushed energetically, and the tramway was ready for the preliminary test on June 10th, but the electrical con-

nections from the power-house of the Los Angeles Aqueduct, which is in Cottonwood Canyon on the opposite side of Owens Lake, were not completed until later. The first bucket of salt arrived at the discharge terminal on July 2d, 1913, and was the occasion for a great demonstration.

The placing of salt at the railroad was a great achievement, and taxed to the utmost the financial capacity of the Saline Valley Salt Company. The reasons for this stringency may be indicated as follows: After the contract was signed, the question of the location of the discharge terminal was an open one for the next 7 months. This indecision as to the terminus of the tramway affected the schedule which was prepared to guide the manufacturer in fabricating and shipping essential parts. It also deranged the plans of the construction crew. Nothing could be done in the making of surveys and the preparation of profiles, designs, or drawings until the site of the discharge terminal was known. Because of this confusion the completion of the contract was delayed beyond the intended date, so that the Salt Company was required to meet the expenses of a construction organization for a longer period than was contemplated in the original estimates.

The contract specified that the capabilities of the tramway should be demonstrated by an operating test of not more than 60 days, under the supervision of the engineers of the buyer and seller. To carry out this provision, active steps were taken by the field engineers to place the specified number of carriers on the line and to co-ordinate the various functions of the machinery, carriers, and signal systems so that the operating test could be undertaken as speedily as possible.

The line worked with great satisfaction when the buckets were loaded about two-thirds full. When efforts were made to carry full buckets, it was noted that the number of accidents due to runaway carriers and others slipping on the traction rope was excessive. An examination of the equipment was immediately started to ascertain the cause. After carefully canvassing all the agencies which might have influenced this unusual behavior of the carriers, the question of the weight of the salt as furnished to the tramway was raised, and an investigation was undertaken to determine the facts. The contract called for the transportation of salt weighing 60 lb. per cu. ft. The

FIG. 11.—TRAMWAY CROSSING DAISY CANYON. ALL PACK TRAINS MUST PASS THROUGH THIS NARROW DEFILE.

FIG. 14.—FLEXIBLE HOODS CONNECTING TRACK CABLE AND DOUBLE-HEADED TRAMWAY RAIL.

actual weights of the salt, as determined by careful tests at the salt field, were as follows:

Air-dried salt	60	lb. per	cu. ft.
Damp salt	65	" "	"
Salt sufficiently moist to agglomerate when squeezed in the hand	68.5	" "	"
Salt when brine is dripping slowly	83.3	" "	"
Salt when brine is dripping freely	90.2	" "	"
When brine is running from salt	94.2	" "	"

It was also noted that the average run of salt from the field was of the wet variety, so that its weight was in excess of 80 lb. per cu. ft. As the weight of saturated salt exceeds by more than 50% the figure stated in the contract, it is evident that the stresses imposed on the tramway had a similar range in value. Unfortunately, they were increments to the stresses contemplated in the original plan. The use of liberal factors of safety in design is again justified, for otherwise this line would have failed under the increased burden imposed. When these conditions were discovered, careful observation of the behavior of the carrier showed that, when carrying dry salt, they traversed the line from the loading to the discharge terminals without noticeable difficulty, but when loaded with wet salt, a few of the buckets would slip on the traction rope. The points where this difficulty was particularly pronounced were between Structures 5 and 6 of Section I; and between Structures 10 and 11 of Section II. There the track cables are as steep as, or steeper than, can be found on any operating aerial tramway using friction grips. In order to indicate the excessive gradients which confronted the designers of this tramway, Table 1 is presented. All gradients of less than 30% have been omitted. This table shows the station numbers of the approved survey, the numbers of the structures, the slope and length of the chord of the span, the number of loaded carriers supported on the span, and the slope, in angular measure and in percentage. These data will be found of great interest, especially to engineers concerned in aerial tramway design. Those who study Table 1 will realize the difficult problems these grades imposed on the designers of the tramway.

To know that this aerial structure is in successful operation is a source of deep gratification to its sponsors. The first great departure

from standard tramway practice was made when the extreme difference in elevation between the loading terminal station and the summit was divided into three sections, and when two sections were used for the descent from the summit to the discharge station. Experience has shown that it is not economical to attempt to utilize traction ropes of large diameter. The total stress developed in such ropes when lifting 20 tons of material 1½ miles vertically at the rate of 500 ft. per min. is so great as to prohibit the use of a single rope for this duty. Multiple traction ropes, arranged in parallel, are not to be considered when a more satisfactory solution of the problem can be developed. Accordingly, it was decided that the tramway should be arranged in sections so as to maintain a traction rope of moderate diameter, and to arrange

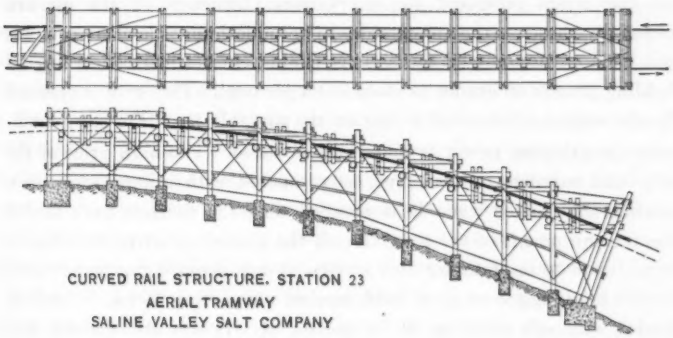

FIG. 15.

the stations so that there would be a constant difference in their successive elevations. It is readily seen that this constant difference in elevation imposes practically the same stresses on the traction ropes of each section. The only feature that is not constant is the friction developed by the moving carriages on those sections which are not of equal length and, consequently, do not support the same number of carriers.

Unfortunately, experience has shown that, irrespective of the constancy of tension in two traction ropes in service, they do not maintain precisely the same diameter. Accordingly, friction grips which have been designed so as to maintain a uniform closure when adjusted to hold satisfactorily on the larger of the traction ropes will slip, all other conditions being constant, when attached to the second traction rope.

By this criterion it was necessary to abandon consideration of the well-known Webber grip for this service. The use of either the Bleichert overhead or underhung automatic grips was taken under advisement. The screw grip, such as Pohlig uses, was unsatisfactory because of the acceleration required to close the gripping lever, which moves in a plane parallel with the direction of motion; also because of the great difficulty in maintaining a proper limit for the throw of the closing lever when operating on ropes of different diameters so as to engage the detacher properly instead of under-running it, an accident which happens frequently on multiple-section lines where this grip is used. The overhead grip was eliminated from further consideration because the extreme tension of the traction rope in passing through structures on the crests promoted the overturning tendency of the carriers, especially those on the empty side. The underhung Bleichert grip was not used on account of the serious doubts entertained concerning its holding powers on grades as steep as 86 per cent. This grip is operated by the weight of the load acting on the movable jaw. On steep gradients the gripping power is materially reduced. The high price of the grip and carriage of this type, as compared with others, was also a considerable factor when it is recalled that 286 carriers were needed for the equipment of the line. As all the accredited grips then known were found to be unfit for this service, it was decided that a new grip should be designed so as to hold carriers supporting 12-cu. ft. buckets loaded with salt weighing 60 lb. per cu. ft. It was also decided that these grips should be of the trunnion type, so that the loads would hang vertically on all slopes; that the grips would compensate successfully without material loss of tractive effort for the different diameters of traction ropes found on the line; that the grips should be of the underhung, top-opening type; and that they should be of moderate cost.

When these grips were furnished and the line was operated, it was found that they fulfilled most of the aims of the design, but, owing to the great variation in the weight of the salt and the consequent increase in drag on the grip, some of them failed by slipping on the extreme slopes. In other words, the requirement for the constant adjustment of grips was too great a hazard to success to comply with the severe specifications imposed by the engineers of the American Steel and Wire Company, who ruled that, because of their uncertain performance when handling the heaviest loads possible, they must be replaced. This

conclusion was reached only after a considerable lapse of time from the date of arrival of the first bucket of salt at the discharge terminal, the reason being that the Salt Company experienced grave financial difficulties which, for about 2 years, prevented running the tramway in accordance with the contract.

Finally, the American Steel and Wire Company voluntarily took over the operation of the line at its own expense, so as to determine what defects, if any, existed, and what replacements should be made. As a result of this investigation, a new grip, called the Universal Wico, was perfected, which has demonstrated its fitness for the duty required. It is designed in strict accordance with the specifications previously outlined, and has sufficient gripping power on the traction rope to handle safely on the steepest grades a carrier loaded to its utmost capacity with the heaviest salt plus the weight of a line rider. It has the additional property of requiring a very light force on the closing lever, and is free from all jars so common to other forms of grips, due to the elasticity imparted to its action by the floating pivot of the closing lever. The grip requires about 40 lb. on this lever to close it. As the carrier has to be attached and detached five times during the passage from the loading to the discharge station, the troubles incident to these operations are five times as great as those on single-section lines, the usual form of the great majority of aerial tramways. In making a round trip on this line the carriers travel more than 26 miles, and a special lubricating system is attached to them so as to provide an adequate supply of oil for the wheels and pins.

Section I is exceptional. From the loading terminal to Structure 4, a distance of 13 550 ft., the line crosses a gradually rising mesa which serves as a fillet between the flat bottom of the valley and the abrupt escarpments of the fault cliffs of the mountain. From Structure 4 onward, the line rises 800 ft. with great abruptness. It is evident that in hauling carriers up a line of this contour the track cables and traction rope must be arranged so that the latter will never carry sufficient tension to cause it to rise above the track cables. Such a condition would be disastrous, as the carriers would be derailed. After careful computations, the tensions were determined so that this section operates perfectly.

Control Station No. 1 is unique in that it is equipped with driving mechanism, tension sheaves, guide sheaves, and a horizontal angle;

and the ends of the building are developed into a pronounced rail structure.

Control Station No. 2 is also equipped with driving mechanism, and presents a reverse vertical curve in profile.

The summit is unusual in that Sections III and IV are controlled from this point, both driving sheaves being mounted on the same shaft. (Fig. 16.) Therefore, the power developed by the descending loads on Section IV assists in raising those on Section III.

As the carriers are being lifted on Sections I, II, and III, there is a possibility of the line reversing its direction of motion, due to the unbalanced weight of the carriers on the loaded and empty sides. Accordingly, each of these stations is equipped with a reverse preventer. This device consists of a large circular plate fitted with shoes containing ball races under the control of a centrifugal governor. When the governor is up to speed, the balls are restrained so that the plates run freely. When the line stops, the balls immediately nip the plate, and a reversal of motion is prevented.

Control Station No. 4 is also equipped with a reverse preventer to stope a retrograde motion of the line in case it is loaded with "back" freight destined for Saline Valley.

The drives of these stations are similar, except that at the summit two sheaves are mounted on the same shaft, as before mentioned. They consist of an 8-ft. grip sheave bolted to a brake run, 7 ft. 2 in. in diameter, with a 12-in. face, and this, in turn, carries an 8-ft. spur gear. The latter is driven by an 18-in. pinion mounted on a shaft fitted with a friction clutch belted to a 75-h.p., Allis-Chalmers, 3-phase, 2 200-volt, induction motor. On Section V this motor acts as a dynamic brake, instead of a driver. A grip sheave is one which carries a special rim, in which there are about ninety-six pairs of toggle jaws. These jaws are held open by gravity or by a special flat spring. When the traction rope passes around the sheave, the pressure developed on the bottom of the groove of these jaws is sufficient to cause them to close and grip the rope tightly. This action increases the friction between the sheave and the traction rope, thereby greatly promoting its efficiency.

The brakes are of the compound differential type, and are actuated by hand-wheels and screws; this method ensures that they will be applied gradually during an appreciable interval of time, so that the

line will not be wrecked because of sudden stoppage, as would be likely to occur with solenoid brakes.

The carriers are of special design, in that the hangers are made longer than is standard, so as to provide proper clearance between the traction rope guide rollers used in the rail structures on the ridges running transversely to the location of the tramway.

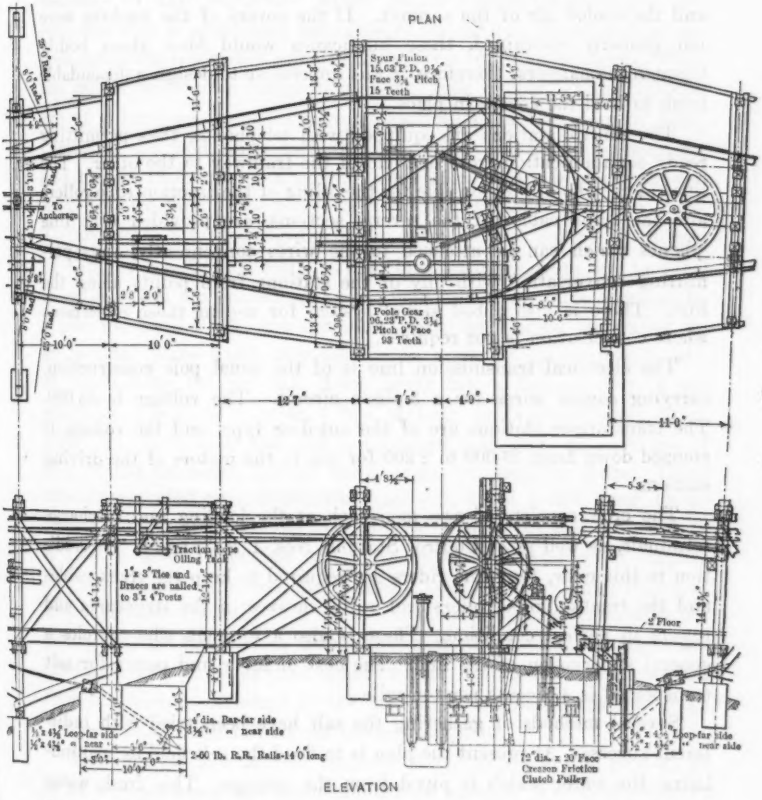

FIG. 16.—PART OF CONTROL STATION NO. 3, SHOWING DRIVES FOR SECTIONS III AND IV.

Owing to the extreme length of the line, it was necessary to cover the salt in order to protect it from contamination due to dust and grease which might drop from the track cable. To obviate the necessity of removing this cover whenever the bucket is dumped, the latter

is cylindrical, and revolves about its trunnions independently of the cover. Owing to the vibration of the carrier in passing through such a great number of stations and structures, it was necessary to provide a very positive keeper to hold the bucket latch in place. In the locality contiguous to the tramway site there are winds of great violence, promoted, no doubt, by the high temperature in the valley and the cooled air of the summit. If the covers of the buckets were not properly restrained, these hurricanes would blow them bodily through the hangers; therefore, it was imperative to design a dependable latch to hold the covers in place.

The control stations are equipped with telephones, thus permitting ready communication from one end of the tramway to the other. The line riders, who are responsible for the oiling of the traction rope rollers and the track cables of the several sections, are provided with line 'phones which can be attached to the wires conveniently, thus permitting conversation with any of the stations from points along the line. There is also a bell signal system for use in those operations where conversation is not required.

The electrical transmission line is of the usual pole construction, carrying copper wires for a 3-phase circuit. The voltage is 33 000. The transformer stations are of the out-door type, and the voltage is stepped down from 33 000 to 2 200 for use in the motors of the driving stations.

The crew consists of two men each at the loading and discharge terminals, as well as at Control Stations Nos. 1, 2, 3, and 4. In addition to this crew, four line riders are required to keep the track cables and the traction rope rollers and guide sheaves in the structures and towers in perfect condition. There is also a foreman who exercies a general supervision of the line. The cost of labor and power for salt transported is 4.6 cents per ton-mile.

Several methods of gathering the salt have been tried with indifferent success. At present the plan is to flood the salt field by manipulating the water which is piped from the springs. This fresh water dissolves the salt rapidly. If the supply of fresh water is then stopped, the evaporation caused by the summer sun is excessive, and pure salt crystals gather in the brine. These crystals resemble flat plates, and are easily shoveled into conical piles about 2 ft. high and 3½ ft. in diameter at the base. Each pile is assumed to contain from 400 to

500 lb. The piles are arranged in rows approximately 12 ft. apart, the spacing between the piles being 6 ft. Mexican labor is found to be most satisfactory in gathering the salt, and each man is supposed to pile from 8 to 10 tons per day. Theoretically, the salt remains in piles until the brine has drained. As the mother liquor contains the majority of the impurities which might possibly contaminate the salt, this step is additional insurance of its purity. However, the salt does not drain freely, but remains damp for a considerable time. When the salt is gathered, a buggy of a special type is used. These vehicles are of galvanized iron and have a channel-like cross-section of body. Owing to the field being soft, the rear wheels are 20 in. in diameter and have a 12-in. face. The front wheels are 16 in. in diameter and have a 4½-in. face. The bed is 3 ft. wide, 8 ft. long, and 6 in. deep. The axles are attached rigidly to the body, so that curves are turned by slipping the front wheels. These buggies carry from 500 to 1 000 lb. of salt, and are hauled across the field by a ⅜-in. cable operated by a gasoline engine. At the dumping point the wagons are pulled up an inclined plane until they assume an angle of approximately 44°, at which slope the wet salt slides freely into a hopper above a car which has a body 30 in. wide, 4 ft. 6 in. long, and approximately 30 in. high. The bottom of this car is hoppered both ways at an angle of 45°, so that the sides, instead of the ends, are used for doors. These cars are operated on a double-track railway, about ½ mile long, by an endless rope haulage system operating at a speed of 200 ft. per min. A 10-h. p. gasoline engine will move seven loads and seven empties on these tracks. The cars dump into a boot serving a drag conveyor which elevates the salt to a point sufficiently high to command the 50-ton bins at the loading terminal. Here the tramway buckets are filled by a lever chute of the ordinary type. The buckets are dispatched from the loading terminal at the tap of an automatic spacing gong. The rate established is fifty-six buckets per hour.

The tramway has carried material continuously at the rate of 23 or 24 tons per hour, and is an unqualified success. The stations, with the exception of the summit, are not housed so as to permit readily of winter operation, but the line is designed so as to prevent snow and other weather conditions from interfering with its operation.

The line is not designed for passenger service, but the line operators use it in preference to going on horseback over the rugged

mountain trails. A ride over this line is a never-to-be-forgotten experience. Starting from either terminal, the passenger rises rapidly to the summit, with a change from the torrid heat of the valley to the chill of the mountain heights. The descent is a reversal of this condition, so that it is difficult to dress properly to be comfortable throughout the trip.

Acknowledgment is tendered to the following gentlemen, to whose individual foresight, skill, and untiring energy are due the design, erection, and initial operation of the tramway: Mr. White Smith, President, Mr. Will Smith, Secretary, W. H. Leffingwell, M. Am. Soc. C. E., Chief Engineer, Mr. Daniel Kuhnle, Superintendent, Mr. M. O. Bolser, Electrical Engineer, and Mr. Harry Hilderman, Foreman of Construction, respectively, of the Saline Valley Salt Company; Mr. J. W. Smith, Local Manager, Mr. S. S. Webber, Chief Engineer (retired 1914), Mr. William Hewitt, Mechanical Engineer, Mr. S. W. Benson, Chief Draftsman, and Messrs. C. H. Wickham, L. T. Hays, and T. J. Murphy, Field Engineers, respectively, of the Trenton Iron Company, and, later, Mr. R. H. Hall, Field Engineer, and Mr. George Hall, Foreman, for the American Steel and Wire Company.

DISCUSSION

Mr. Lamb.

RICHARD LAMB,* M. AM. SOC. C. E.—On studying this paper, with reference to other plants which have been built, it is seen that it describes novel features and conditions which were overcome with difficulty.

At first one might wonder that such an expensive plant should be constructed for handling so common and cheap a commodity as salt, for a 7½-lb. bag of the best grade retails at present for 10 cents, and lasts a family for quite a time. During normal times much salt is brought to the United States as ballast for vessels, and is sold at a low price.

Recently, the speaker was examining a cement stone deposit in Alabama, and found, at a point 3 miles from tide-water, a salt deposit from which most of the salt used by the Confederate States was mined during the Civil War. A comparison of the plant described by Mr. Carstarphen with a project to mine salt and deliver it by cableway to tide-water from the Alabama deposit indicates that the latter would have a great advantage. Later, the speaker visited the Gulf Coast of Louisiana, and there found that vast deposits of salt are now being mined and shipped by boat or train with little or no intermediate transportation, and the owners cannot sell all they can mine. However, it is presumed that the market was examined before the Saline Valley cable tramway was built.

One of the novel features of this tramway is its excessive gradients; the speaker knows of no other long cable tramway where they are so steep. The only other plant in the United States which can compare with it in length is that of the American Copper Company, in Wyoming, 16½ miles long. In the latter, however, the maximum vertical angle is about 20°, as compared with 40° in the Saline Valley plant.

The undertaking was bold, in that such gradients had not heretofore been overcome, and the success of the plant would depend on the efficient service of the grip used. The speaker would have thought that the Pohlig grip would have been successful; however, the author states that the plant was not equipped with either the Pohlig or the Bleichert grip.

In the Bleichert system the difficulty, on steep gradients, is that in going up the steepest incline of the cable, just before surmounting the saddle at the tower, the hauling cable is pulling somewhat downward, and the resultant force has a tendency to retard the carriage. In the system designed by the speaker, the hauling cable is kept parallel with the bearing cable, and the downward pull is practically

* New York City.

Mr. Lamb.

obviated. This feature is used on the line of the American Copper Company.

The speaker's discovery of this principle was due to the following incident. A patented logging cable tramway had been erected by parties who stated that it was practical. The bearing cable was carried on A-frame supports. A trolley carriage ran on the cable, and from it the log to be transported was suspended. Attached to the log was a cable which was made fast to a whippletree drawn by a horse. As the trolley approached the cable support, it had to ascend the incline caused by the inherent sag in the cable. This direction was one line of force in the parallelogram of forces. The direction of the pull by the horse was horizontal. The resultant force, consequently, was downward, and the trolley would not pass over the support. The project was a failure, and the difficulty could not be overcome under the conditions of the system.

If a trolley trackway is on a grade and a rope is attached to the trolley to pull it in a horizontal direction up grade, the trolley will not move. It is necessary to have the hauling and bearing cables as nearly parallel as possible. The steeper the gradient, the more difficult this problem becomes. Practical plants embodying this principle were described by the speaker some years ago in a paper* before this Society. An inherent feature of cable tramways is that they must be built in an absolutely straight line. In the logging cable tramway described by the speaker, in the paper referred to, the sheaves carrying the hauling cable were hung so as to permit the alignment to deviate from a straight line, but it had to be very nearly straight.

In the Saline Valley line there are three changes of direction, or four separate cable tramways joined by curved rail at the points of deflection, with electric motors to operate the hauling cable at each angle. At each control station the traction cable is made a unit for that station only, and is driven by its own motor. The summit station is arranged so that both the grip sheaves are on the same shaft, and are controlled by a motor which supplies the difference between the power required to hoist the ascending bucket and that developed by the descending bucket. The power is not transmitted around curves, as in surface cable-power street railroads.

The tension ordinarily used on cable tramways is about 30 000 lb. per sq. in. of cable. The cable can never be stretched to approach closely the horizontal; if so, it would be strained beyond its elastic limit. The towers are usually about 250 ft. apart. Tension stations are about 5 000 ft. apart. In some cases spans as long as 1 600 ft. between towers have been operated successfully.

* *Transactions*, Am. Soc. C. E., Vol. XXXII, p. 44.

Mr. Lamb.

The Chilcoot Pass cableway was built mainly for the transportation of passengers. For years this Pass had been traversed by miners and others seeking gold, and it was so difficult that many lives were lost there. The Trenton Iron Company built a cableway that carried freight and passengers successfuly over the Pass. It was intended to build the power plant on a plateau, named White Horse, near the center of the Pass, but an avalanche buried the site, and it was with difficulty that another could be found.

The power was furnished by a porcupine boiler in which the tubes were of such weights as could be carried to the site by Indians. The bearing cable could not be more than $\frac{3}{8}$ in. in diameter, as it also had to be transported by Indians. The transportation from Trenton to the final location was more expensive than the material of the plant. Great care had to be exercised in making the cable, as there was one span about 1 500 ft. long. The first person to traverse the line was a girl who used her canoe as a car.

Mr. Scholtz.

H. F. SCHOLTZ,* ASSOC. M. AM. SOC. C. E.—There are several places in the Pacific Northwest where tramways for transporting logs are in successful operation. The logs are taken out from places practically inaccessible by any other method. One instance is in the Cascade Mountains, near Index, Wash., where logs as large as 6 ft. in diameter are carried across a deep ravine and down a precipitous cliff to the mill.

Mr. Carstarphen.

F. C. CARSTARPHEN,† M. AM. SOC. C. E. (by letter).—The writer appreciates the favorable tenor of the discussion which has been presented. Several points mentioned by Mr. Lamb are worthy of note. The first deals with the question of the price of salt, which no doubt was of great importance to the promoters of the Saline Valley Salt Company, but was only of passing interest to the builders of the tramway. Information as to the prices which can be obtained for salt on the Pacific Coast shows that they range from $3.50 to $40.00 per ton, depending on the grade and character. Ocean salt sells for about $3.50 per ton, which is somewhat less than the computed retail price of $26.70 per ton for salt, at the rate of 7½ lb. for 10 cents. It is the writer's understanding that milled salt suitable for table use sells wholesale at from $16 to $20 per ton, so that with the ample demand of the fisheries and other users of salt on the Pacific Coast and in the Northwest territories, the development of the Saline Valley salt field was considered by its promoters to be a worthy business enterprise.

Mention has been made of the length of the tramway built for the American Copper Company, of Grand Encampment, Wyo. The writer quotes from a report on file relative to this line:

* Carrollville, Wis.
† Trenton, N. J.

Mr. Carstarphen.

"The tram was built in four sections of about four miles to each section. The first section from the smelter to Station 1 was approximately four miles in length, with a raise of perhaps 4% across an almost level prairie. The buckets were transferred there from Section 1 to Section 2, etc. Section 2 was almost four miles, and the first three miles above Station 1 was a gradual raise of probably 4 per cent. For the last mile of Section 2 the raise was probably 12%, and crossed one or two deep gulches. Station 2 to Station 3 was over a rough broken country. It consisted of long spans and some very high towers. From Station 3 to the loading station the tramway crossed the Continental Divide. Station 3 was in a canyon, and the mine was also in a canyon. The tramway line raises probably 3 000 ft. between the two terminals along Section 3.

"This tramway is of the old Leschen lug type; one of the first four cable tramways built by that company. The lugs consist of a piece of sheet steel bent around the cable and a cast-iron button or lug riveted into this steel, and this button in turn entered into channel irons on the buckets by means of triggers and slide bars. There is one of the same type of tramways at the Sunnyside Mine, Silverton, Colo.

"The cables on the tramway at Encampment were of the 6 by 7 lang lay type, and probably 1⅛ or 1¼ in. in diameter. The traction ropes were ¾ in. in diameter.

"Tram was driven by power generated from boilers located at the various stations along the line.

"Mr. Riblet was on the ground, and designed the structures and figured all the towers, angles, and deflections of the cables. Equipment was all furnished for this line by the A. Leschen and Sons Rope Company, of St. Louis, Mo.

"The traction rope on these towers was supported by small sheaves which hung on a cross-beam 21 in. from the top of the stationary cable. These sheaves were grooved, and when the buckets passed over the sheave the lug would raise the rope high enough to pass between the rope and the sheave. One main difficulty was this: These channel irons on the buckets were bolted to the frames with ½-in. carriage bolts, two on each side, or four bolts altogether. The track ropes were so slack that the buckets in passing over the long spans would hang down so low that the traction rope would pull the lugs through these irons, breaking off the bolts and letting the buckets run away. The lug, being riveted to the cable, would immediately whirl over a few times and, as it passed, the next tower would hang on a rod that supported the timber for the tower sheave. Towers were all set on the ground without any anchorages, and consequently it dragged this tower to the next one and then hooked onto that one and pulled it to another one. Sometimes the writer would go up along the line and find as many as four towers all piled up in one bunch. The engines were powerful, and the man in charge had no idea when anything was hung up. They just kept pulling as long as they could move the thing.

"The downward pressure on the traction rope in coming over the Continental Divide, caused by the driving station and the loading station being in the canyon below, and long spans leading to each

one of them, was so great that it would simply cut through a new tower sheave in a very few hours. We experienced most of our difficulties in the operation of this tramway on the three miles of country adjacent to the Continental Divide." Mr. Carstarphen.

The topography, due to the erosion of the Bridger sandstones, is not comparable with the faulting and mountain-forming tendencies which have developed the extreme slopes and elevations characterizing the mountainous areas of California; and, therefore, the difficulties of design of the two tramways are not of the same order.

No difficulties were experienced on the Saline Valley tramway due to the faltering of the carriers in passing the saddles supporting the track cables, on account of the traction rope not being parallel with the bearing cable; nor is this tendency of any importance on tramways of the Trenton-Bleichert construction, for it is eliminated by the fundamental principles of tramway design. Reference to Fig. 6, which represents loaded and empty carriers passing an 80% grade, will show that the track cables and traction rope are practically parallel.

In modern tramway design, it is customary to place the cable supports so that the angle formed by the intersecting tangents developed by the chord slope and the deflection of the empty and loaded cable, is kept within a reasonable amount, depending on the radius of the saddle and its capacity in angular magnitude.

The tensions used in tramway track cables have changed from time to time. Twenty years ago track cables were erected with a tension as low as 14 500 lb. per sq. in. Tensions were then increased to 22 500, 25 000, and 30 000 lb. per sq. in. Beyond this stage increased knowledge was obtained of the stresses developed in locked coil cables due to bending. The influence of frictional hysteresis on the modulus of elasticity of the cable in bending was ascertained, so that the question of the proper tension of a tramway track cable depends largely on the condition of the particular tramway which is being designed.

If it is admitted that stress, due to bending, is developed in the outermost wire of a track cable, it is consistent to assume that a cable can be made to fail due to excessive bending only. It is well known that, if sufficient direct stress is developed in the cable, it can be pulled in two. Therefore, there is an economic tension to be applied to the track cable which will develop a minimum combined stress in the outermost wire due to direct load and bending.

Bending stress is developed in the track cable due to its support of the loaded carrier. The measure of this bending is a cable curve. The tangent of the intersection angle is equal to the weight of the load divided by the horizontal component of the tension in the track cable. If the loaded carriers are low in weight and the tension in the track

Mr. Carstarphen.

cable is high, the intersection angle of the curve under the carrier will be small; that is, the curve will have a long radius, and the stress developed in the outermost wire, due to bending, will be less than that due to direct tension.

This is the fundamental criterion which should be considered in designing aerial tramways, where it is desirable that a proper life of track cable should be obtained, together with a minimum of interference due to improper elevation of tower saddles.

The spacing of the towers depends on the tension in the track cables and the weight of the load supported. With a proper radius for the saddle supporting the track cables, the spacing of the towers depends on the economic construction height of these supports. The farther apart the towers are, the greater must be their height in order to balance the deflection and clearance required between the bottom of the carrier and the ground surface. The longest span which the American Steel and Wire Company has put in is 3 600 ft.

Tension stations may or may not be used, at the designer's option. In fact, it is customary to control the change of position assumed by the track cable when loaded and empty by erecting it as an anchored span. It is well known that the product of deflection and tension at any point on a suspended cable is constant. Accordingly, in anchored spans, if the loading changes, the deflection tends to remain a constant, due to the change in tension. If the cable were non-elastic and symmetrically loaded, there would be no change in deflection between the empty and loaded positions. In practice, there is a slight change in these positions, due to the elastic properties of the cable.

The pronounced limitation of tramway location to a straight line is no longer apropos, as present-day designers do not hesitate to handle moderate angles on the tramway supports. In this manner angles of considerable magnitude may be introduced into the alignment of the tramway without interfering seriously with its operation; nor is it necessary in cases of this sort to build a special structure called an "angle station."

Although the discussion has not been extensive, it has served a useful purpose in demonstrating that the proper design of aerial tramways is based on sound principles of engineering, and that such systems of transportation are not to be considered as expedients to be adopted when no other method can be used. Aerial tramways are safe, sane, and satisfactory.

Paper No. 1395

THE WATER SUPPLY OF PARKERSBURG, W. VA.*

By William M. Hall, M. Am. Soc. C. E.

With Discussion by Messrs. John W. Hill, Alexander Potter, George W. Fuller, Nicholas S. Hill, Jr., Walter E. Spear, T. Kennard Thomson, H. F. Dunham, Theodore S. Johnson, Philip Burgess, James H. Fuertes, Morris Knowles and J. D. Stevenson, Edward Mayo Tolman, and William M. Hall.

Synopsis.

This paper describes the process of selecting a new water supply for the City of Parkersburg, W. Va., the investigation of the possible sources of supply, especially the natural underground supply in the neighboring Ohio River bottoms and plateau, the physical and geological phenomena relating thereto, the methods considered for collecting the water for pumping, and the novel method finally adopted, which consists of an infiltration system composed of strainer pipes laid in the bed of the river and overlaid with a bed of washed gravel and sand.

Introduction.

The City of Parkersburg, W. Va. (population 17 842 in 1910), constructed works for a public water supply in 1884. The pumping station was established on the banks of the Ohio River, and for more than 25 years the supply was drawn from the muddy and polluted waters of that stream, and used for all purposes without any treatment whatever. With increasing quantities of sewage entering the river from Pittsburgh, Wheeling, and other communities in the Ohio Valley

* Presented at the meeting of February 21st, 1917.

above Parkersburg, this supply became increasingly unsatisfactory. Typhoid fever was quite prevalent, and investigations in 1906 and 1907 indicated for that disease annual death rates of 75 and 60, respectively, per 100 000 population.

In 1907 a law was enacted creating for Parkersburg a Water-Works Commission, composed of three city officials, including the Mayor, and four citizens, of whom the writer was one.* This Commission instituted investigations for the purpose of determining the best method of treatment of the Ohio River water, if that should continue to be the supply, and whether or not water could be obtained from wells, cribs, or from a gravity source. As a part of the project, consideration was also given to a new pumping station to supersede the original plant, which had suffered much from wear and tear in pumping muddy water for such a long time. It is not within the scope of this paper to describe the details of the pumping station, distributing reservoirs, pipe lines, etc.

Preliminary Investigations.

Morris Knowles, M. Am. Soc. C. E., was engaged to make recommendations relative to a new water supply. In addition to gravity and impounding sources of supply and filtration of the Ohio River water, he investigated the feasibility of obtaining a well-water supply from the Camden Farm, which lies immediately north of the upper city limits of Parkersburg. This is shown by Fig. 1.

Mr. Knowles reported in August, 1908, for a recommended 4 000 000-gal. daily supply, that, although the well proposition was attractive, further investigation should be made, perhaps in other localities, or somewhat removed from the Camden Farm. His test of a 12-in. well did not indicate a serious lowering of the ground-water level, but, for safety, a more elaborate test was recommended, as it was realized that a large factor of safety should be required in establishing a well plant. Based on his recommendations, the citizens voted on April 22d, 1909, to authorize a bond issue of $270 000 to build the proposed new water-works; and he was authorized to prepare plans and specifications for the construction thereof.

* The Commission consisted of Messrs. W. D. Pedigo, Mayor, C. D. Forrer, of the Board of Affairs, Walter Gerwig, Councilman, and the following citizen members: Messrs. S. D. Camden, H. H. Moss, B. S. Pope, and the writer. Mr. Camden was elected President of the Commission, and Mr. Forrer, Secretary. After the expiration of Mr. Forrer's term of office, Mr. George P. Chase, Attorney, though not a member of the Commission, served as Secretary.

FIG. 1.

Some doubt as to the permanency of the well-water supply arose in the minds of some of the city officials, and, on request, further consideration was given to the matter in July, 1909, by Mr. Knowles, who called in Mr. F. G. Clapp, a geologist, as advisor on this subject. Mr. Clapp favored the well-water supply, but was also aware of the possibility of having to build new wells in future years, thus making it wise to secure at the outset plenty of land in the vicinity of the projected plant; such additional land would also protect the purity of the supply by avoiding surface pollution near the wells.

There was still one member of the Water-Works Commission who was unable to agree with the otherwise unanimous opinion as to the adequacy of the proposed well supply and its suitability as to quality. To obtain further data, James H. Fuertes and George W. Fuller, Members, Am. Soc. C. E., were engaged in November, 1909, to investigate and report on the proposed well supply, with a view to settling the differences of opinion between the city officials and the citizen members of the Water-Works Commission. They investigated the well-water project with considerable thoroughness, and found that, though it would be possible to obtain a 4 000 000-gal. supply from the gravel and sand layers underlying the bottom-lands in the neighborhood of the Camden Farm, it would be necessary that such a well system should extend along the river for at least 4 000 ft., thus making its cost greater than that of a filtered-water supply from the river. They recommended the adoption of the latter.

The city officials passed an ordinance authorizing the Board of Affairs to build the filtration works and appurtenances, but this authorization was nullified by an injunction suit which stopped the further expenditure of funds, made available by the bond issue for the purpose, without the approval of the Water-Works Commission. In the meantime Mr. L. E. Smith interested some of the leading citizens in a system of water supply consisting of a manifold of pipes laid in a sand bar in the Ohio River. Samuel M. Gray, M. Am. Soc. C. E., was then engaged to report on the advisability of adopting the so-called Smith system. His report, delivered on May 26th, 1910, being favorable, the works were built under his direction, and for 5 years or more the water has been clear, clean, and of satisfactory sanitary quality. Not only has the new water supply been satisfactory to the citizens, but it is gratifying to note that the new pumping equipment has effected

an economy sufficient to pay the capital charges on the bond issue required by the new plant.

It is believed that the development of the new supply has placed on record many data of general interest to the Profession with regard to ground-water; and that this is so with respect to the investigation of the well-water supply by Messrs. Knowles, Fuertes, and Fuller, and in particular in the case of the somewhat novel system built by Mr. Smith under the direction of Mr. Gray. In placing before the Society the principal features of the Parkersburg water project, the writer feels of necessity bound to make liberal use of the reports of the above-mentioned gentlemen, and wishes to state that much of the following is an abstract compiled from their several reports in the preparation of which he is indebted to them.

Geological Conditions.

The geological conditions of the Ohio Valley in the vicinity of Parkersburg were investigated at length by Mr. Knowles with the aid of Mr. F. G. Clapp.

Attention is first directed to the cross-sectional profile of the Ohio River at Lock and Dam No. 18 (Fig. 2), furnished by the writer from investigations made under his direction.

The bottom-lands on the West Virginia bank of the Ohio River, for a distance of 5 or 6 miles north of and above Parkersburg, contain more or less water-bearing strata. This is shown by numerous wells in successful use for domestic and manufacturing purposes within that tract, and is also confirmed by an examination of the materials removed in drilling these wells.

From a study of the history of the Ohio River in this immediate locality, it appears that the river bed has shifted its position materially along the part south of the promontory at Briscoe, where the rock of the West Virginia shore extends down to and beneath the river bed. At present the Ohio lies well to the west in the river bottoms, in some places nearly reaching the foot of the hills forming the rugged upland of the Ohio shore. In earlier days the river unquestionably skirted the West Virginia foot-hills. The result of this shifting has been the deposition of a substantial quantity of gravel and sand in the present bottom-lands, with a stratum of sandy gravel extending north from above the upper limits of the City of Parkersburg for about 5 miles, and having a varying width averaging perhaps ¾ mile.

FIG. 2.

This stratum varies in depth from perhaps 15 to 25 ft., and averages approximately 20 ft., according to available information. It is overlaid with a stratum of loam ranging in depth from 25 to 40 ft. The bottom of the sand and gravel stratum varies in elevation roughly from about 540 to 550 ft. above sea level, and its top surface from about 560 to 570 ft.

A more detailed statement of the local geology, with comments on its significance with reference to the ground-water supply of Parkersburg, is set forth with various comments by Mr. Clapp in the following paragraphs.

Local Geological Details.—In order to make sure of the adequacy of the present and future supply, the formation of the valley and its sediments was carefully considered. The real bottom of the Ohio Valley is not the present surface of the river or of the first and second bottoms, but is the bed-rock surface, or surface of the solid rock (sandstone and shale) underlying these. Along the part of the valley considered, this bed-rock surface lies from 50 to 125 ft. or more below the first bottoms, as determined by the depth of numerous wells and test borings.

The origin of the buried bed-rock surface is due to erosion at a time—thousands of years ago—before the overlying gravel filling existed, when the whole country stood higher above the ocean level, and hence the present bed-rock was at the surface of the ground. The deeper parts of the bed-rock valley (*i. e.*, those now buried more than 100 ft. below the present bottoms) were eroded by the ancient Ohio River as it cut its way deeper into the surface of the country while it was comparatively high, forming a sort of gorge below the general level of the bed-rock surface in the valley. Thus there were (and still are) three rock levels: (1) that of the gorge, now from 100 to 125 ft. below the present first bottoms; (2) that of the ordinary bed-rock in the valley, now from 50 to 90 ft. below the first bottoms; and (3) that of the surrounding hills, the tops of which stand from 200 to 300 ft. above the bottoms. The sand, gravel, and clay filling which forms the bottoms and higher unconsolidated terraces along the valley was formed at a more recent date than the rock valleys, due to various incidents in connection with the Ice Age, during which the northern part of the territory now occupied by the State of Ohio

was covered with a great glacier, damming the river valleys at various places.

For the most part, the buried bed-rock surface of the Ohio Valley is rather flat, and, under the Camden Farm and elsewhere, it lies from 50 to 90 ft. below the lower bottoms. On this rock bench rest the water-bearing gravels, from 20 to 30 ft. thick, from which it is proposed to draw the water supply by pumping from wells. The gravels are covered by clay, fine sand, and loam, reaching to the surface of the bottom-land. Many household wells driven into the gravels, and also geological inferences, have shown that the formation is similar and continues for miles up and down the main valley.

No part of the rock gorge underlies the Camden Farm, but at this place it is below the present river. Presumably it meanders from side to side of the valley, and farther up and down stream it may underlie the gravels, as it does at the test wells on the land of the Parkersburg Iron and Steel Company. In order to show that this deeper gorge will not interfere with the supply of the wells by draining off the water at a lower level, it may be stated that the deeper gorge is filled for the most part with finer material, such as fine sand and clay, and these do not hold large volumes of water. Moreover, the portion of the underflow of the river which follows the gorge is separated from the water in the upper gravels by layers of finer, more impervious material, which tend to keep the two bodies of water separate.

Another geological feature which needs consideration is the terrace known as the "sand plains region", lying back of Boreman Hill, and standing at an average elevation of 80 ft. above the first bottoms, or 130 ft. above the underlying bed-rock. The sand plains are about ½ mile wide, and extend from the bottom-lands of the Ohio Valley at Beechwood for ½ mile to Worthington Creek. It is a geological fact, based on good evidence, derived from what is known of similar sand plain regions at various places along the Ohio, that this strip was the ancient valley of Worthington Creek, or the Little Kanawha River. The depth of the sand and gravel filling there is unknown, but it is considerable; and through shallow wells which have been drilled there, it is known that it contains a large volume of water. This water is supplied by the rain which falls on the sand plains and flows westward, through the underlying sand and gravel, to the Ohio Valley,

where a large part of it passes through the gravels underlying the Camden Farm.

Thus there will be two sources of supply for the wells: the ground-water from the sand plain district, and that from the bottom-lands in the main valley of the Ohio, both bodies of water moving toward the wells. At no other locality in the vicinity could this double supply be obtained in such great quantity.

Gravel-Water versus Rock-Water.—The question arises: Can a better or more adequate supply of ground-water be obtained by drilling to some lower level than is planned, that is, into the bed-rock? To this question the reply is decisively "no". The rocks underlying the river valleys and the entire vicinity of Parkersburg are similar in character to those in the surrounding hills, and consist of shales and sandstones of the Dunkard formation (upper barren coal measures), which contain very little water, and nowhere in these rocks could a sufficient supply be obtained. In fact, a supply as large as is necessary does not seem to exist anywhere in the shales and sandstones of the coal measures, or in the thin limestones scattered through them. Many hundred feet below the surface of the valley, a large enough supply could be found in limestones, but, even if it was practicable to sink wells to that depth, the water would be found to be salty and unfit for use.

Estimated Yield of the Wells.—Calculations by Mr. Clapp agreed with those by Mr. Knowles, that fourteen wells will yield from 3 000 000 to 4 000 000 gal. of water per day, which is more than is at present needed, and will suffice for some years to come. However, after from 8 to 12 years, it may be necessary to add a new well every year or two for several years, in order to keep pace with the increase in population and to replace possible deteriorating wells. Hence, plenty of land should be secured in the vicinity of the wells. Owing to the character of the water, and the known type of river gravels, the wells may last 15 years or more without the necessity of being replaced. In order that the supply may be maintained at approximately its initial quantity, the wells should be cleaned occasionally, and, if pumped with an air-lift, the air pressure should be reversed frequently, in order to blow out any fine material which may collect in the pores of the gravel close to the wells or in the strainers.

Arrangement of the Wells.—The water in the gravels is moving in two directions. A part of it, derived from the rainfall on the bottom-lands farther up the valley, is moving slowly down stream, approximately parallel to the Ohio River. A second part of the gravel-water, derived from the rainfall on the sand plains, is moving from them toward the river, in general at right angles to it. Therefore, the proposed arrangement of the wells in two lines, one parallel to the river and the other at right angles thereto, is the best for securing all available water. The wells should be at least 300 ft. apart.

Hydraulics of the Local Well-Water Field.

So much discussion having arisen in Parkersburg as to the relative merits of a well-water supply and a filtered-water supply from the Ohio River when Messrs. Fuertes and Fuller made their examination in the fall of 1909, it was determined to conduct pumping tests for a period of at least 3 weeks. Accordingly, a deep-well pump was set up in one of the 12-in. wells sunk by Mr. Knowles. This pump was operated under the observation of James R. McClintock, M. Am. Soc. C. E., from January 18th to February 8th, 1910, and during this period quantities ranging from 480 000 to 575 000 gal. daily were pumped. Eight special observation wells were driven, and frequent studies were made of the water level therein, and also in thirty-one existing driven wells within 3 or 4 miles up the river on the Camden Farm site, including two wells in the sand plains east of the bottom-lands.

Water levels in the river were taken several times a day, and samples of the well water were collected frequently for analysis. The temperature of the well water was uniformly between 51 and 52° Fahr., and that of the river water during the period under observation ranged from 34 to 38° Fahr.

Summary of Results of Studies of Ground-Water Supply, as to Source, Quality, and Quantity.

The results of the pumping tests are given in a report by Messrs. Fuertes and Fuller, dated February 21st, 1910, with perhaps unusual clearness, and a summary of this information is given at some length, as follows.

Water-bearing Strata.—The first essential in securing a ground-water supply was to ascertain the conditions with respect to the water-bearing strata, as it is obvious that without such strata a ground-water supply for the city was out of the question. Reference has already been made to the local geological conditions, and these may be further spoken of from the standpoint of water supply as to the character of the water-bearing strata.

The elevation of the Ohio River opposite the Camden Farm ranges from about 562 at low water to about 621 for extreme high water, which floods the bottom-lands to a depth of from 10 to 20 ft. At low water the depth of the river varies somewhat, but approximates 5 ft., according to the surveys made by the United States Government.

The present river bed opposite the low lands in question is made up largely of sand and gravel. The proportion of gravel and the range in gravel size vary considerably. The proportion of sand apparently increases with the distance from the natural dam at Briscoe.

Excellent building sand for local construction work is secured from the river bed by dredging at a point opposite the Camden Farm. Samples of this sand, after removing the gravel by screening, show what would be called a medium river sand, having an "effective size" of about 0.28 mm. Test wells sunk by Mr. Knowles, and from which samples of material were placed on exhibition in the rooms of the Water Commission, show a substantial proportion of relatively fine or medium-sized gravel from which the sand was largely eliminated in the process of removal from the ground. So far as it has been possible to ascertain, these bottom-lands, at a depth of about 40 ft. below the surface, contain a sand and gravel layer with the sand predominating. The sand is of medium size, filling the voids of the gravel and thus controlling the resistance of the stratum to the flow of water. The average depth of the layer is about 20 ft., and not more than one-fourth of it is above extreme low water. In a rough way, it appears that during dry years the water in the river is below the level of the surface of the sand and gravel stratum for about 4 months, and sometimes it is 3 or 4 ft. below for weeks at a time.

Deep wells show that, beneath this water-bearing stratum of sand and gravel, there are layers of shale and clay, rather irregularly spaced, and interspersed with more or less sand and gravel. So far as it has been possible to ascertain, however, the sand and gravel layers below

the main deposit are too thin and too variable as to continuity to make them worth serious consideration in connection with a municipal water supply.

The general conditions as to the present river bed at Lock and Dam 18, about 2 miles below Briscoe, are shown on the sectional profile, Fig. 2.

Source of Ground-Water.—The second step in studying a ground-water project was to ascertain the source of the water found in the water-bearing strata, and particularly the source and direction of the flow of water in such strata in the event that a municipal supply were to be taken regularly therefrom.

Inspection of local conditions shows at once that the promontory at Briscoe, with the rock extending across the river a short distance beneath the river bed, clearly precludes the possibility of any substantial quantity of ground-water coming from points above Briscoe and passing longitudinally down the bottom-lands. Accordingly, a water entering the sand and gravel strata must come either from the river, by infiltration through the bottom and sides of the river-bed, or from the rainfall on the bottom-lands themselves or the upland district immediately tributary thereto.

Inspection shows that these bottom-lands are traversed longitudinally by Pond Run for the greater portion of the distance, and at the upper or northern end there is another run which passes diagonally across the bottom-lands and enters the Ohio at Vienna. These surface streams have a drainage area of some 5 sq. miles back in the hills. The hilly sections contain much clay and loam, and are generally of an impervious character, as distinguished from the so-called sand plains. Pond Run apparently has an almost impervious bed. Its slope is exceedingly light, and the fine materials deposited show that, except at times perhaps of heavy rainfall, no appreciable quantity of water passes from this run into the water-bearing strata below.

Along the edge of the upland area there are a number of flowing wells and wet places, showing clearly that the water entering the ground in the hilly upland district meets impervious strata as it reaches the edge of the bottom-lands, and that it is easier for it to force its way to the surface than to enter the sand and gravel strata.

Of course, some rainfall on the bottom-lands themselves would reach the underlying strata of sand and gravel, but the fine and impervious

nature of the 40-ft. layer of loam precludes this from reaching any substantial volume. It must also be borne in mind that the loam stratum is flooded with muddy Ohio River water from time to time, and the surface at such periods is covered with a deposit of fine silt and clay.

During wet weather, perhaps when the water in the Ohio is high, it would appear that the water contained in the pores of the extensive sand and gravel layers is largely from the river, but to some extent it is from upland sources, the high river stage damming up some of the upland water.

Messrs. Fuertes and Fuller were firmly of the opinion that, during low-water stages in the Ohio, the water which can be drawn from the strata is that which has been stored within the pores of the material at times of previous high water. They were also certain that, during low stages in the river, as this stored water is removed or naturally flows away, whatever water enters these sub-surface strata of sand and gravel is largely of river origin. They concluded, therefore, that, as a source of supply for a municipality, the water from such strata, at the end of protracted droughts, must come from the Ohio through the bottom or sides of the present river bed along the bottom-lands below Briscoe.

Disposition of Ground-Water.—The next point on which it was necessary to make inquiry, in studying the feasibility of a ground-water supply, was the answer to the question: Where does the water entering the porous sand and gravel layers in question now go? The answer is shown clearly by the studies which have been made and the profiles of the water levels secured from different wells prior to the occurrence of high water during the winter of 1909-10, as well as in the study of various water levels or contours during and subsequent to the January rise in the Ohio. Unquestionably, the water in the porous sand and gravel layers, found at some distance below the bottom-land, ultimately makes its way more or less irregularly and slowly into the Ohio.

Several features of interest and importance were disclosed in studying the question of the relation between the passage of the water from the Ohio into what is practically a large underground storage reservoir, as above described, the water storage therein, and

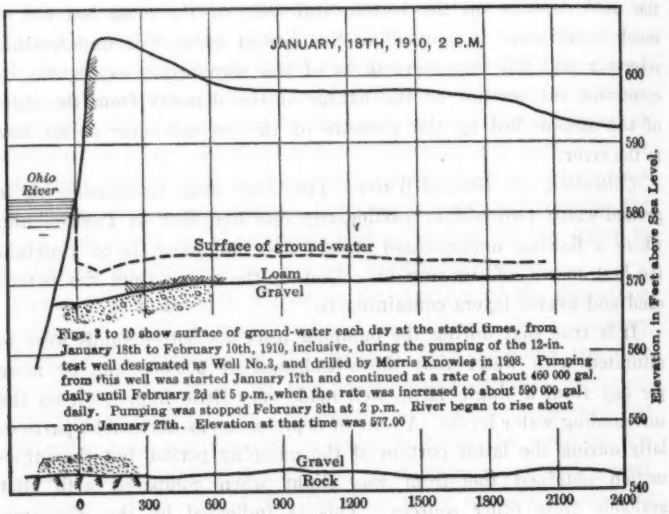
also the passage of water therefrom back into the river. This is indicated by the diagrams, Figs. 3 to 10.

In the first place, it was found that the water in the porous sand and gravel layers did not rise to such high levels as those found in the river itself. This is indicated by the readings in test wells almost at the bank of the river; and shows that, even during fairly high velocities in the river, there is still so much mud and silt deposited on its sides and bottom that a considerable head is required to overcome the friction sufficiently to allow substantial quantities of the water to pass through this thin and more or less impervious deposit.

In the second place, in discussing the question of the disposition of the water stored in these sand and gravel layers, it is necessary to consider the character of the material, and especially the finer particles of sand making up the water-bearing stratum or underground storage reservoir. In this regard the observations showed that considerable head was required in order to cause the water to flow in substantial quantities through the sand interspersed with gravel. For instance, it was found that the river water scarcely affected the level of the water in wells 2 000 ft. from the river, notwithstanding that in the river itself there was a 20-ft. rise during the period in which the observations were made.

This shows two important features: one is that this underground reservoir fills from the river only to a slight extent during floods of short duration; the other is that considerable water cannot be removed at a single point without creating quite a steep slope on which the water will flow to the point of removal. This means that the water stored in this underground reservoir can by no means be removed entirely; in fact, in order to remove a substantial portion, it would be necessary to establish points of withdrawal at quite frequent intervals throughout the area in question.

Pertaining, however, to the answer to the main proposition set forth under this heading, it may be said that the water stored in this sand and gravel layer during floods makes its exit into a falling river with quite steep slopes when the quantity stored is great. Considering these underground sand and gravel layers as a storage reservoir, therefore, it is seen that, after having once been filled during a protracted flood, the reservoir, in the absence of any pumping, slowly becomes emptied as the river falls. Here it may be pointed out that, although



the mud deposits on the bottom and sides of the river bed are of much significance in controlling the rate at which this underground reservoir will fill, they seem to be of less significance as regards its emptying, on account of the lifting of the deposits from the sides of the stream bed by the pressure of the ground-water in its flow to the river.

Collection of Ground-Water.—The next step in considering a ground-water proposition, particularly one like that at Parkersburg, where a flowing underground stream does not exist, is to ascertain the best means of drawing or collecting the water from the porous sand and gravel layers containing it.

It is true that during the pumping tests the bottom-lands were so saturated with water that the withdrawal of 500 000 gal. or more per day from a single 12-in. well made very little impression on the surrounding water levels. A cone of depression was noticeable, particularly during the latter portion of the pumping period, but the information obtained therefrom was slight when compared with that available from other sources. This is indicated by the diagrams, Figs. 3 to 10.

The studies by Messrs. Fuertes and Fuller showed clearly that during the pumping period, from January 17th to February 5th, 1910, the ground-water contours were nearly parallel to the river. In other words, there was substantially no difference in the elevation of the ground-water at approximately equal distances back from the river throughout the entire length of the bottom-lands. This fact tends to show that the quality and porosity of the underlying porous strata of these lands are not materially different throughout their length. It also shows that there is no substantial flow of water longitudinally through the porous strata forming the underground reservoir in question. Therefore, they concluded that it would not be judicious to provide for the removal of ground-water by a line of wells at right angles to the river bank. This is shown by Figs. 3 to 10.

The records obtained by Mr. Knowles in December, 1908, show that, even when less than 350 000 gal. per 24 hours were pumped from a 12-in. well, the water level was lowered in the well about 13 ft. without lowering the surface materially at points less than 200 ft. from the well. Furthermore, this cone of depression had its apex below the surface of the rock on which the sand and gravel strata rest.

Figs. 3 to 10 show surface of ground-water each day at the stated times, from January 18th to February 10th, 1910, inclusive, during the pumping of the 12-in. test well designated as Well No.3, and drilled by Morris Knowles in 1908. Pumping from this well was started January 17th and continued at a rate of about 460 000 gal. daily until February 2d at 5 p.m., when the rate was increased to about 590 000 gal. daily. Pumping was stopped February 8th at 2 p.m. River began to rise about noon January 27th. Elevation at that time was 577.00

FIG. 10.

The volume of water which could be pumped from this well at the end of this protracted period of low water, therefore, was limited by the flow which could reach the bottom of the sand and gravel strata at any given location for the removal of water; at the point in question the limit seemed to be less than 500 000 gal. daily.

These data led to the conclusion that it would be less advantageous to attempt to place an underground collecting gallery at or near the bottom of the porous strata in question than to collect water by a series of wells, assuming that the investment cost would be kept at about the same figure.

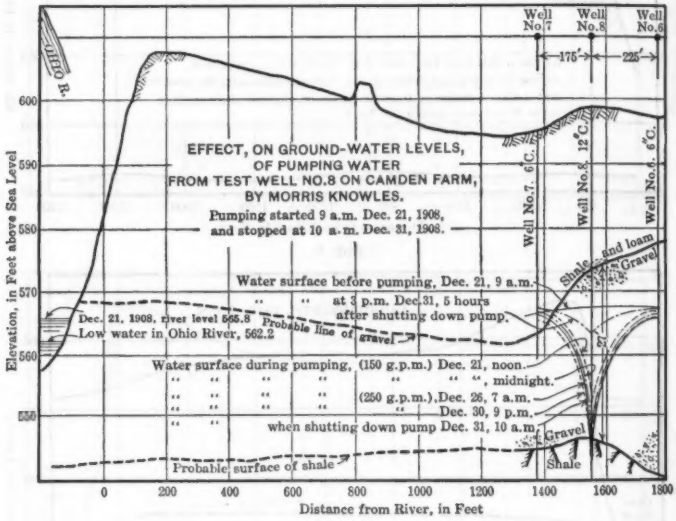

FIG. 11.

Taking everything into account, and considering only the geological conditions, it is perfectly clear that the best method of collecting an underground water supply from the district in question would be by a series of wells, each not less than 10 in. in diameter, parallel with the river, and approximately 400 ft. apart.

Mr. Knowles' recommendation for a line also perpendicular to the river was influenced by the lay of the land which was being given to the city by the Senator Camden estate provided the land was used for water-works purposes.

Furthermore, as a safeguard during protracted periods of drought, it was the opinion of Messrs. Fuertes and Fuller that it would be wise to sink these wells in a line parallel to and about 200 ft. from the bank of the river, rather than at a greater distance, and not at right angles thereto.

Available Quantity of Ground-Water.—The investigations of Messrs. Fuertes and Fuller showed clearly that, during high and moderate stages of the Ohio, a supply of ground-water ample for all needs of the city exists in the porous sand and gravel layers in the bottom-lands above the Camden Farm.

It was also their opinion that it was reasonably certain that, at the end of low-water periods, a well-designed system of wells would provide for the needs of the city for some time to come.

To obtain a supply of 4 000 000 gal. daily from wells, it would be necessary to provide at least ten wells of the size and positions above mentioned; and further, in order to insure this volume of water at the end of protracted periods of drought, it would be essential to provide a plant for increasing artificially the quantity of water filtering in from the river, through its bottom and sides, to the wells in question. Messrs. Fuertes and Fuller considered it possible to secure an increase of infiltration by means which are noted subsequently in describing the feasible methods of securing a ground-water supply under local conditions.

Quality of Ground-Water.—During the Fuertes and Fuller investigations particular attention was paid to the quality of the water, both as shown by the results of analyses of samples made during Mr. Knowles' investigations, and also of analyses of samples taken during the pumping tests and analyzed jointly by Professor Merriam, of Marietta, and by Mr. J. R. McClintock, who served as Resident Engineer during these tests. In brief, these analyses showed a water which was of excellent appearance, and satisfactory in every way for domestic and manufacturing uses. There was a slight tinge of turbidity in the well water when examined in 1-gal. bottles, but it was so slight that it would not be noticed in a tumbler. At times of increasing suddenly the rate of pumping, or on starting up the pump after it had been shut down for a few minutes, slight increases in the turbidity were observed, but these quickly disappeared.

FIG. 12.

All samples analyzed were tested, without any effort to eliminate the slight turbidity mentioned.

Briefly stated, the bacteria in the well water ranged from 14 to 170, and averaged 63 per cu. cm. The total hardness of the well water ranged from 76 to 98, and averaged 90 parts per million. The river water samples collected on the same days showed a total hardness ranging from 52 to 71, and averaged 63 parts per million. Corresponding figures for wells in the Beechwood district were 88, 102, and 94, respectively.

Samples of well water taken from the test well were analyzed carefully for iron, and found to contain about 0.5 part per million. There was no sign of this iron precipitating out, and experience elsewhere shows that, with the quantity of iron above stated, difficulties are not encountered.

Samples of water taken from test wells contained rather objectionable quantities of iron in some instances, evidently due to the water dissolving iron during long intervals of standing in contact with the metal.

Slightly increased quantities of iron were found in the water of the well at the steel works, but not to an objectionable degree. This greater quantity of iron is explained partly by the flow of water through a long line of pipe and partly by the connection which the well has with underground porous strata where the water remains in contact with pervious layers for many months and perhaps years.

Messrs. Fuertes and Fuller, taking everything into consideration, had no hesitancy in stating that the quality of the water from the porous sand and gravel layers of the bottom-lands at and above the Camden Farm is thoroughly satisfactory for domestic and manufacturing purposes. They placed the water from such wells in the same general class as filtered water obtained from a properly built and well operated filter plant treating water from the Ohio River in the vicinity of Parkersburg.

There are some slight differences in the quality of the water from wells and from filters, the principal feature of which would be the hardness on account of the wells yielding water coming largely from the Ohio River at times when it is in flood and fairly soft. Messrs. Fuertes and Fuller did not attach much importance to this difference, because ultimately, during low-water periods, the well water would

also have its source in the Ohio. So far as quality is concerned, they put waters from filters and from wells in the vicinity of the Camden Farm on a parity. However, the writer is somewhat partial to the natural water when equally free from bacteria and other objectionable qualities.

MOST PRACTICABLE METHOD OF SECURING A GROUND-WATER SUPPLY.

Messrs. Fuertes and Fuller discussed and considered from various viewpoints the most practicable method of securing a ground-water supply, and their conclusions may be briefly summed up as follows.

It is not feasible to secure a municipal water supply for the City of Parkersburg by galleries or wells running at right angles to the Ohio River.

Wells of very large diameter, or tunnels, would not be a fruitful investment, on account of the steep slopes of the cones of depression which would be formed around the points of withdrawal of water. Small wells, not less than 12 in. in diameter, afford by far the best way of collecting the ground-water supply from the porous sand and gravel layers in the bottom-lands at and above the Camden Farm.

These wells should be in a line parallel to the river, about 400 ft. apart, and about 200 ft. from the bank.

A deep tunnel for receiving the flow of the wells is far less expedient than a force main receiving the waters from individual wells, due to the expense of tunneling at the depths required, and other local conditions.

DESCRIPTION OF WELL-WATER SYSTEM AS CONSIDERED BY MESSRS. FUERTES AND FULLER.

The studies of the plant necessary to carry out most economically and advantageously the methods just described of securing a ground-water supply from the locality in question, are briefly described as follows.

Extent.—Ten wells should be established, in a line extending along the river front, approximately 200 ft. from the bank, and 400 ft. apart.

Location.—As the well layout would cover about 4 000 ft., it is not feasible to place all the wells on the Camden Farm, or, in fact, all below the Steel Works, as the porous underground strata do not extend a sufficient distance down stream. It is assumed, therefore, that the well plant will extend to above the Parkersburg Iron and

Steel Works. Prudence, however, would suggest that they should not reach above the lower end of Neal's Island, on account of the shallowness of the channel east of that island, the absence of scouring velocities therein, and the imperviousness of the stream bed.

Wells.—It is contemplated to sink shafts, 7½ ft. in diameter, brick lined, and 40 ft. deep, or down to the top of the porous sand and gravel layer. In each there should be a cased well, 12 in. in diameter, with a brass strainer for a length of at least 20 ft. at the lower end. This 12-in. pipe would be connected with a centrifugal pump placed at the bottom of the 7½-ft. shaft, the masonry wall of which would be extended up to above extreme high water, some 12 ft. above the ground level in this locality.

Comparison of Well-Water Supply with Filtered Supply from the Ohio River.

In the report of Messrs. Fuertes and Fuller comparative estimates of cost were given, both for the well-water supply and filtered river-water supply to provide an average daily yield of 4 000 000 gal. and be capable of supplying water for short periods at a maximum rate of 6 000 000 gal. per 24 hours.

In substance, this report stated, on the basis of figures detailed therein, that the cost of construction and of operation of a first-class well system and a first-class filter system at the Camden Farm site were substantially on a parity as to the quality of water and as to the cost, both of construction and of operation, and that either plant could be depended on to supply such quantity of water as would be needed by the City of Parkersburg for some years to come. Mention is to be made of the fact, with reference to the well-water supply, that the estimates of cost include a suitable charge for land required to insure the adequacy of the system.

Further, the report stated that, by placing the filter plant nearer the site of the present pumping station, the investment cost could be made less for the filter plant, but with no substantial difference in operating and maintenance expenses between either plant at either site. The report finally recommended that all interests of the city would be best served by the establishment of a filter plant, near the site of the then existing water-works pumping station, to supply the city with properly filtered Ohio River water.

Smith Infiltration System.

An injunction suit, as already stated, prevented the city officials from acting independentiy of the full Water-Works Commission in building the proposed filtration system, as above recommended. Then, at the request of various prominent citizens of Parkersburg, the Smith system came up for consideration.

In May, 1910, Mr. Samuel M. Gray, reported on water-works improvements with special reference to the so-called Smith strainer-pipe system of filtration, his conclusions in brief being as follows:

1.—This system, under local conditions, is both feasible and practicable for furnishing an ample supply of water of suitable quality for the present needs of the city.

2.—If properly built and operated, this system will furnish water of a better quality than a mechanical filter plant, as regards steam-raising purposes, on account of the slight increase in permanent hardness which is caused by the use of a coagulant.

3.—Though higher in first cost than a mechanical filter plant, the operating cost of the Smith system would be materially less, amply so, in fact, to warrant the higher first cost.

4.—That water from the proposed driven wells would be inferior in quality to that from the Smith system, and, further, that such wells would be very likely to lessen in yield in course of time, and the water grow harder and contain more iron, with also the possibility of local contamination from surface sources.

On considering this matter further, Mr. Gray modified the detailed plans by recommending that the infiltration system should be divided into five units, with a separate suction pipe for each unit. The advantage of this was to facilitate back-flushing of the sand overlying the respective units of pipe manifold systems, and for making repairs and renewals without affecting seriously the service to the city. This recommendation was authorized, and, for the sake of economy, it was decided to abandon the so-called Camden Farm site and build a new pumping station on the river bank nearest the site selected for the infiltration system in order to economize in the cost of suction pipe. The relative locations are shown on Fig. 1.

Mr. Gray suggested using a greater length of slightly smaller strainer tubes, in order to increase the strainer surface. He also pre-

pared the plans and specifications for the construction of the infiltration system, as well as for other improvements to the water-works plant.

Contracts were then let for the infiltration system, and the work progressed to completion under the direction of Mr. Gray and according to the plans and specifications prepared by him. Mr. W. G. Wheelock was Resident Engineer.

Unusual Features of the Contract for the Smith Infiltration System.

As there had been considerable skepticism regarding the successful working of the Smith system, no similar works of comparable size having been in operation, the contract was made unusually exacting. Only 45% of the value of work done was paid on monthly estimates, the remainder being retained until 30 days after the test period of 364 days after the beginning of successful operation, as guaranteed. The contractor made the following guaranties for the system:

1.—The capacity to be 170 000 gal. per hour;

2.—The supply to be satisfactory, to the Water-Works Commission and the Board of Affairs, for domestic and industrial uses;

3.—The water to be of pleasing appearance, practically clear and colorless, and to contain not more than 5 parts per million of turbidity;

4.—With 3 000 bacteria per cu. cm. in the raw water (or higher), the filtered water to contain not more than 3% of that number; with less than 3 000 per cu. cm. in the raw water, the filtered water to contain not more than 100 per cu. cm.; counts to be on agar plates incubated at 20° cent., for 48 hours;

5.—Filtered water to contain on an average not more than 30 parts per million of total hardness in excess of Ohio River water;

6.—Iron in solution not to exceed 0.7 part per million;

7.—The foregoing requirements to be shown by daily tests covering period of 364 days from the date of beginning operation.

In case of failure to comply with the guaranty, the city was under no obligation to pay the retained 55%, and the completed plant was to become the property of the city.

The contractor was required to maintain the plant in good condition and thorough repair until acceptance.

CONSTRUCTION DETAILS OF THE SMITH INFILTRATION SYSTEM.

Under the contract, three units were completed and put in service on November 12th, 1911. The other two units were completed and put in service on December 15th, 1912. The plant has been in continuous operation ever since, except for 4 days during a flood which broke the former highest record by 5 ft., and thereby partly submerged the boilers and engines.

Fig. 13 shows the arrangement of the pipes in the infiltration system, and illustrates the appearance of the units while being laid.

The site of the plant is on the lower end of the bar at the foot of Vienna Island, at a point where the natural top of the bar forming the bed of the river is about 1 ft. below the low-water level. By inquiry, and the examination of Government hydrographic maps made about 10 years previous to the preparation of the plans, it was concluded that this bar had been practically stable for many years.

The system of five units of filters was placed by using two cofferdams of the ordinary box type common on the Ohio River lock and dam construction; and the suction pipes to the power-house were laid in an open trench, with the excavated material banked on each side. The work was done during the low-water seasons of 1911 and 1912, with the top of the coffer from 7 to 8 ft. above low water.

At this point the fluctuation of the water is about 58 ft., and stages up to 40 ft. are of annual occurrence. Coffer No. 1, enclosing Units 1 to 3, was built and removed in 1911, and Coffer No. 2 in 1912.

In the unwatered coffer the excavation for the pipes was made to 5½ ft. below low water. On the floor thus formed a 6-in. layer of gravel was placed, on which the pipes were laid and covered with 12 in. of gravel; on the gravel a 3½-ft. layer of clean washed sand was laid, bringing the top of the sand to within about 6 in. of the low-water line, or a few inches higher than the natural surface of the bar.

The infiltration system of five units thus formed is 110 ft. wide and 656 ft. long (1.65 acres), and is 5 ft. deep. The gravel was the washed and screened Ohio River product which passed a 1½-in. mesh, and with the sand removed. The sand was taken from the Ohio River and washed, and is fairly sharp and coarse. The filter

PLAN OF FILTER SYSTEM

FIG. 14.

thus constructed lies in a natural sand bed of great dimensions, as described previously. It is the writer's opinion that a very large percentage of the water drawn is taken from the sand bed, possibly a larger part than that from the open river.

Each unit of the filter system contains 32 brass strainer pipes, 16 ft. long and 5 in. in diameter, or 160 pipes in the five units. Each pipe is perforated with 9 400 V-shaped slots, 1⅜ in. long and about $\frac{1}{70}$ in. wide.

From each unit to the gate-chamber there is an 18-in. cast-iron suction pipe, each of these pipes forming a small reservoir. They are connected with the pumps by one 24-in. cast-iron suction pipe. This arrangement prevents serious trouble by the production of a vacuum in the suction pipes, with the resulting flow through the filtering material at an undesirably rapid rate.

Cost of the Smith Infiltration System.

The cost of the complete water-works improvements, including the infiltration system, is indicated in the following statement:

Water-Works Construction Fund.

Contracts Nos. 1 and 2:		
New mains including laying	$45 626.15	
Connecting service pipes to new lines	2 883.91	
		$48 510.06
Valves and hydrants		5 936.53
Pumps		32 442.30
Boilers		8 055.30
Pump well		21 556.67
Pumping station		11 441.32
Brick chimney		1 374.43
Laying pipe (force main)		5 021.27
Pipe and castings (force main)		15 987.01
Valves, etc. (not covered by No. 3)		2 394.63
Infiltration system		80 700.03
Venturi meter		772.10
Electric light plant		1 953.81
Plumbing and heating		555.72
Stand-pipe		2 029.65
Carried forward		$238 730.83

Brought forward		$238 730.83
Pumping station lot	$1 700.00	
Expense, sale of bonds	9 131.30	
Tests for water supply	2 435.20	
Refund to water-works fund, on account of preliminary engineer's report, test wells, etc.	5 000.00	
		18 266.50
Amount paid to engineers:		
Preliminary reports and well tests		10 419.39
Design and supervision of construction		11 801.92
Miscellaneous expenses, Water-Works Commission, Not chargeable to above items:		
Office rent and expenses, clerk, Dr. L. O. Rose testing water, electric wiring to pumping station, and miscellaneous expenses		4 952.58
		$284 171.22
Cash balance, January 31st, 1914		2 658.76
		$286 829.98

The cost of operation is indicated by the following:

For the fiscal year, July 1st, 1912, to June 30th, 1913:

Salaries and wages at pumping station	$5 541.00
Fuel at pumping station	3 319.61
Oil, packing, etc., at pumping station	889.76
Repairs and improvements at pumping station	2 142.09
	$11 892.46

Average pumpage per day..... 2 955 000 gal.
Total pumpage for year..... 1 078 675 000 gal.
Cost.....$11.03 per million gallons.

The records for 1914 and 1915 show a slight reduction in this cost.

The expense of operating the filters in 1915, including flushing the five units 73 times, is estimated by the Superintendent's office as $673. The average quantity of water used for each unit at each

flushing is 40 000 gal. Although the tank capacity is 60 000 gal., it is the custom, in operation, to use 40 000 gal. at each flushing. The cleaning and flushing is practically all the expense which has been incurred in excess of pumping out of the open river. The time required to pass the 40 000 gal. through a filter is from 15 to 20 min. When pumping out of the open river with the old plant, some trouble was caused by ice, leaves, etc., but it is believed that the cost of pumping from the filters and keeping them cleaned is no greater than that of pumping from the open river.

The maximum pumped in one week in 1915 averaged 3 760 000 gal. per day and 154 166 gal. per hour. For 2 weeks after the great flood of 1913, the average pumpage and consumption exceeded 5 500 000 gal. per day.

The water has shown a little turbidity about three times, at river stages of about 45 ft. The writer has observed turbidity in that drawn from his service pipes only once.

From May 1st, 1913, to January 31st, 1914, daily tests of the water were made under the direction of the Commission by Dr. L. O. Rose in his laboratory at Parkersburg, and report thereof is shown in part in Appendix I. This report shows that the quality of the water produced by the filters conformed in every respect with the terms of the contract.

From time to time since making this series of daily tests, Dr. Rose has made tests of the water, and the data obtained by him for the calender year, 1915, are included in the Appendix. The water has been tested by numerous others, but the writer did not, until the summer of 1916, hear of a report indicating that it is not as good as required under the contract.

A recent report of it, prepared for the City of Wheeling, W. Va., has questioned its being of the highest standard. Since March, 1916, samples of water have been shipped monthly to the West Virginia State Bacteriologist, at Morgantown, W. Va., for test. Of about 14 shipments, several, when tested after standing a day or more, have been reported "unsafe". From February 15th to October 27th, 1916, Dr. Rose tested 38 samples and found *Bacillus coli* present in 11, and absent in all the others. For each of these 11, 2 tests were made of 1 cu. cm. and 10 cu. cm. each. In 3 of the samples *coli* were present in both tests, and in the other 7, it was absent in the 1 cu. cm. Of the other 27

samples, the two tests were made for 19 of them and only the smaller quantity for the other 8.

On account of these reports, early in September, 1916, Mr. Gray was engaged to have all the filter beds examined and cleaned. He assigned G. H. Leland, M. Am. Soc. C. E., to carry out this work personally, and Mr. Leland was engaged in doing this for nearly a week. The writer spent several hours with him on his second day of inspection. At several places there were holes in the sand and gravel covering. The holes were from 5 to 10 ft. in diameter, and were formed like craters. They extended down to within 1 or 2 ft. of the level of the brass strainer pipes. The work done under Mr. Leland's supervision consisted of stirring the deposit on top of the filter beds with a powerful force pump, at the same time giving each section numerous back-flushings, and thereafter filling the holes with fresh gravel and sand. In the 10 samples tested by Dr. Rose since that work was done, no *coli* were found. Of these 4 were tested in both 1 cu. cm. and 10 cu. cm., as previously explained, and the other 6 in only the smaller quantity.

The writer is of the opinion that tests should be made at regular intervals, weekly or more frequently; but, on account of the confidence in its quality, it appears that such an important work to safeguard the health of the community has not been done regularly.

Under date of June 10th, 1913, Mr. I. L. Birner, Bacteriologist, certified to Contractor Smith, after a series of tests in a laboratory at the pumping station, that:

"An examination of the results of 400 separate analyses of the filtered water at the Parkersburg filtration plant, made between January 23d and June 4th, 1913, covering a widely varying set of conditions, from a river stage at 5.8 to 58.9 ft., and with a river turbidity varying between the extreme limits of 15 and 1 950 parts per million, shows a clear water, with an average total hardness of 10.5 parts per million in excess of the river water; the total iron in solution, of the filtered water, was 0.19 of one part per million, against an average of 5 to 16 parts in the river, and a bacterial removal, or bacterial efficiency, of 98.28 per cent."

Until recent years an accurate count of typhoid cases in the city has not been available. However, the public impression is that, previous to 1912, the yearly number was comparatively very large.

For 1915 there were twenty-two cases which started in the city and ten cases which were brought in after illness commenced, making thirty-two cases in all. Of the twenty-two, three were traced to a well, three were railroad employees, and one was a United States clerk, and these men were out of the city much of their time.

Dr. Stone, the City Health Officer in 1914, informed the writer that all the typhoid cases in the city that year except four were traced definitely to other causes than the city water.

Dr. Rose has stated that not one recent case of typhoid has been proved to have come from the city water supply, and this report is confirmed by Mr. Nearn, City Health Officer, whose present duty includes an investigation of the cause and history of all such cases. However, the monthly reports of typhoid cases in 1916 show a little higher numbers than for 1915.

Thus far, the system has been entirely satisfactory to the citizens. Its success has been fully equal to the most sanguine hopes of the writer when, as a commissioner, he voted for its adoption. However, he realizes that the experimental stage is not past.

Three units are now ending their fifth year of service, and the other two their fourth, with comparatively little indication of failure in quantity, or in the quality of the water.

However, the writer knows that it is only a question of years when the sand and gravel over the strainer pipes will have to be replaced by fresh clean gravel and sand; the principal question being the number of years before this will become necessary in order to maintain the good quality of the water. He is also impressed with the great importance of vigilance and care in its operation, and of systematic daily or weekly tests of the water.

APPENDIX I

Report of Tests of the Water from the Filtration Plant and the Ohio River, for January, 1914.

By Lonzo O. Rose, M. D., Parkersburg, W. Va.

The results are given in parts per million.

	Date.	Turbidity.	Alkalinity.	Incrustants.	Total hardness.	Iron.	Bacteria per cubic centimeter.	Rate of pumping.	Vacuum.	Stage of river, in feet above low water.

DISCUSSION

Mr. J. W. Hill.

JOHN W. HILL,* M. AM. SOC. C. E. (by letter).—The writer has read with interest this paper on the recent improvement of the Parkersburg Water-Works. Having had the honor of making the original plans for the Parkersburg Water-Works Company in 1881, and later of revising these plans and constructing the original water-works in 1884, he is naturally more or less familiar with the location and history of this improvement.

The original works, planned by a company of which the late Senator J. N. Camden was a member and the leading spirit in the enterprise, looked almost exclusively to fire protection for the city and the furnishing of water to railroads and manufacturing enterprises; in fact, at that time, 36 years ago, little attention was paid to the hygienic qualities of water supplies in America.

The Ohio River water in its then polluted condition was accepted for drinking purposes by all the cities taking water therefrom. The dangers lurking in sewage were not then well known, and in some respects not suspected. Time, research, and experience have since demonstrated that the Ohio River water in its natural state has not been suitable for drinking purposes for many years, if it ever was.

The Smith system of filtration has been proposed for several cities along the Ohio River and came prominently to the writer's notice while he was the Engineer Member of the Ohio State Board of Health, when it was proposed as a mode of supply for the City of Portsmouth, a few years ago. At that time, as well as before, the proposition was studied and classed as an artificial sand and gravel filter, and it was thought that such a filter, placed beneath the bed of the river—or rather below low-water stage in the river—beyond reach and examination, during ordinary and high stages, would not satisfy the modern requirements of a filtered water supply.

Plain sand filters, such as are used at Philadelphia, Pittsburgh, Washington, and other places in the United States, and used extensively abroad, are constructed so that they may be under constant observation as to the performance of each particular unit, and when the loss of head has reached a maximum—or other conditions suggest—they can be taken out of service, the sand beds can be scraped and rehabilitated, and the filters restored to their original condition and efficiency. The Smith filters, however, can be examined and repaired only at long intervals, and, if it should occur that the quality of the water obtained from them was unsatisfactory during a period when the stage in the river was considerably higher than the sand bars in which the filters are placed, there would be no relief from the unsatisfactory quality

* Cincinnati, Ohio.

Mr. J. W. Hill

of the water except that which might be obtained from back-flushing the collecting pipes, and that, in the writer's opinion, is always a doubtful method of restoring filters to normal condition.

It was also thought, in connection with the Portsmouth proposition, that, in view of experience with water purification systems somewhat similar to the Smith filter along the Ohio River, there was no assurance, at any time, that the quality of the water would satisfy strict sanitary requirements, and, for this reason, objection was then made by the Ohio State Board of Health to the adoption of this system by Ohio cities.

At several places in the paper Mr. Hall mentions a possible source of water supply to wells from the Ohio River, on the assumption that the water will pass through the silted bed of the river and reach the wells through the sand and gravel in which the latter are driven.

From long experience, with wells along the Ohio River and elsewhere, it is the writer's conviction that wells or galleries sunk below the bed of the adjacent river seldom, if ever, receive water from it. Many tests for hardness, chlorine, and iron, in water from the wells and from the river or stream, have always shown a distinct difference, and, in the writer's experience, this has been sufficient to indicate that the water from the wells is not naturally filtered river water. This experience has been so uniform over a wide range of territory, and throughout a long period of time, that it has led him to conclude that water obtained from wells or infiltration galleries along a stream is always land-water or ground-water percolating through, or pocketed in, the pervious strata, some of which in due time reaches the stream in the form of springs. In a case where a surface connection is made from the river to the porous material in which wells are driven, the water may percolate through the porous material and reach the wells in this manner, but the writer can recall no considerable success, either from experience in America or abroad, in obtaining large volumes of satisfactory water in this way.

Considering the Parkersburg wells proposed by Messrs. Knowles, Fuller, and Fuertes, the writer would assume that all the supply furnished by these would be obtained from the water moving toward the river from the land side, or pocketed in the porous material along and under the river bed; and though the stages of the river will have an influence on the elevation of this ground-water, it would not imply any flow from the river to the wells.

Several years ago the writer had occasion to test the influence of continuous pumping for 2 months from a gallery or well sunk in a gravel bed along the Iowa River, and, for the purpose of defining the extent of the water field, several observation wells were driven at distances ranging from 100 to 8 325 ft. from the gallery. A level

Mr. J. W. Hill.

base and bench-marks were established, and the levels of the water in the gallery and in the observation wells before and during pumping were noted from time to time and carefully referenced to the base. The pumping was continuous, day and night, for 62 days, and the elevations of the water in the gallery and in the observation wells, at the beginning, during, and at the end of this period are shown on Fig. 15.

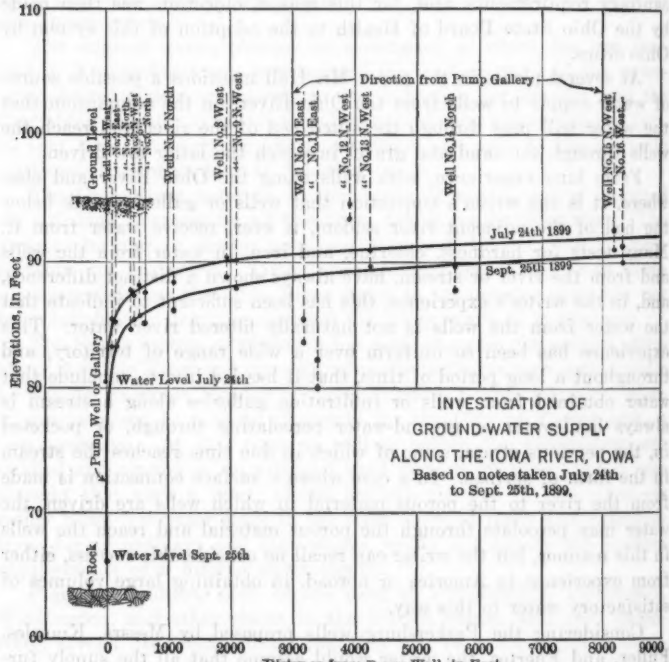

FIG. 15.

Although the test wells shown on Fig. 15 range from 100 to more than 8 300 ft. in a direct line from the pumping well or gallery, they were distributed east, west, and northwest from it, so as to include the water field which it was thought would be affected by the test. Fig. 15 shows some curious results, with reference especially to observation wells Nos. 10, 11, and 12, all of which were open and penetrated the sand and gravel water-bearing strata, and in which the water levels fell from time to time during the test.

Mr. J. W. Hill.

Though the water in No. 12 dropped 1.20 ft. during the 62 days of pumping, at the end of the period the surface of the water therein was considerably above the general elevation of other wells nearest to it in point of distance and in the same general direction from the pump well (northwest).

On the other hand, the water level in Nos. 10 and 11, which were east of the pump well, was at no time as high as in the nearest wells in point of distance, although not lying in the same direction from the pump well. The only explanation for this discrepancy that could be given at the time of the test was that the wells were on lower ground and nearer the river, and might have been supplying the river rather than the test pump well. In attempting to draw smooth curves on the diagram for the elevations at the beginning and end of the test, Nos. 10, 11, and 12 were omitted, all the others lying sufficiently near to a smooth curve to indicate the probable water level at the beginning and end of the test.

"Reference to the diagram, upon which have been plotted the elevations of water in the pump well and observation wells, will show the mean curve of water level which existed in the known area affected by pumping on September 18th. All water in the field above this curve has been pumped away or lost by natural causes, and for the rate of pumpage from the test pump well at that time [693 000 gal. per day] this curve represents the average condition throughout the field.

"The facts obtained from the experimental work [in Iowa] conducted during the summer [1899] are as follows:

"The total amount of water pumped from the test well from July 24th to September 21st, inclusive, was 38 796 662 gal., an average of 646 600 gal. per day. During this interval of time, from the data submitted, the water level in the test pump well was lowered from Elevation 87.78 to Elevation 73.93, or 13.85 ft.

"The total rainfall reported after July 24th aggregates 6.03 in., and, applying this to the area embraced in the investigations, *viz.*, 1 367.4 acres, and allowing an absorption of 40% by the sand and gravel overlying the rock and under the top soil and clay, the absorbed rainfall within the field of observation amounts to 89 555 837 gal., or more than twice the pumpage from the test pump well for the interval of time during which the rainfall was reported.

"The loss of head or lowering of water level from all causes within the field of observation during 57 days of pumping was approximately 2 ft., equivalent to a loss in the field of 235 251 147 gal., to which add the estimated absorbed rainfall, making the total estimated loss from all causes 324 806 984 gal., of which the pumpage from the test well was about 12 per cent."

An interesting part of Mr. Hall's paper relates to the cost of the Smith system of filtration. This is stated as $80 700 for a capacity of 170 000 gal. per hour, or 4 000 000 gal. per 24 hours, or more than $20 000 per million gallons of daily capacity. This is a very high cost

Mr. J. W. Hill. for a system of filtration of this kind. Elaborate slow sand filters of the type adopted by Philadelphia, Pittsburgh, Washington, etc., cost no more, and are of such a character that the operation may be observed from day to day, and controlled in capacity and efficiency; and rapid mechanical sand filters would have cost at Parkersburg (in 1911) about one-half as much per million gallons of capacity as the Smith system.

The performance of slow and rapid sand filters can be fully controlled, and maintained at high efficiency, regardless of river stages and other unavoidable conditions which are calculated to operate against sand filters of the Smith type.

The guaranty of 4 000 000 gal. per day for a total area of 1.65 acres is equivalent to 2 426 000 gal. per acre per day, or about the capacity of plain sand filters operating without any preliminary filtration.

The manner of making payments for the Parkersburg filter was unusual. A retention of 55% of the contract price for one year after completing the construction indicates that there must have been a sublime faith, on the part of the contractor, in the final performance of the filter system.

Mr. Potter. ALEXANDER POTTER,* ASSOC. M. AM. SOC. C. E.—The City of Parkersburg is to be commended for its courage in putting in operation the so-called natural slow sand filtration method of procuring a supply of pure water. This method has been advocated so vigorously by its proponents and has been opposed so bitterly by its antagonists that a plant of this kind actually constructed should prove of a distinct advantage in demonstrating what is of scientific value in the plan and what of a distinctively personal bias on both sides of the much controverted subject.

The speaker has watched with much interest the attempts which have been made from time to time to solve successfully the problem of so-called natural filtration. There can be no doubt that the successful establishment of such a plant will meet with popular favor, and therefore such a project should be given a fair and impartial trial.

The speaker recalls that on an invitation for competitive plans for a new water supply from the City of Evansville, Ind., in 1893, fourteen or fifteen engineers submitted plans. In this competition George S. Davison and W. G. Wilkins, Members, Am. Soc. C. E., were awarded the first prize, the speaker received the second prize, and Arthur S. Tuttle, M. Am. Soc. C. E., the third prize. The plan recommended by the speaker was submerged filter galleries on a sand-bar in the bed of the Ohio River, and, as he recalls it, most of the fourteen competitive plans contemplated similar treatment.

* New York City.

Mr. Potter.

Though the speaker's project was not developed by the city, the study made at that time convinced him that, given proper river conditions, infiltration galleries can be designed to give a uniform and pure effluent.

The uniformly good results secured in temperate climates, however, by rapid or slow sand filtration, clearly limit the field of operation of the so-called natural slow sand filtration process, or infiltration galleries, to places where the cost of the latter—the first cost plus operating charges—is less than mechanical or slow sand filtration. In the tropical zone, however, a strong prejudice exists—and rightly so—against the use of stored water, even when filtered; consequently, the development of a supply from infiltration galleries warrants a higher cost than is involved in the construction of mechanical filtration with adequate storage.

Though the analyses of the water included in the paper show a satisfactory effluent, they represent, unfortunately, only a limited period. From the statement made by the author, it appears that radical changes must be introduced in the details of the system in order to prevent a recurrence of the condition found when the beds were examined after having been in service about 3 years. The author states that conical holes were discovered in the sand, having diameters of from 5 to 10 ft. and from 3 to 3½ ft. deep.

It is evident that at all stages of the river, except extreme low water, difficulties will be experienced in maintaining a uniform depth of sand over the filters, and that, under certain conditions beyond the control of the operator, raw water in large quantities may pass directly into the city supply, thus breaking down the barrier against typhoid fever. If no adequate remedy can be provided, either to prevent blow-outs due to back-flushing, or to restore positively and promptly the sand over the strainers when such blow-outs occur, the system particularly described by the author must be considered a failure, no matter how successful it may be most of the time.

With Messrs. Gray, Hall, and others, standing sponsor for the success of the Parkersburg system, it is to be hoped that the best and most intelligent care will be given to its proper maintenance, and that every effort will be made to correct the defects already apparent, which prevent it from producing a uniformly dependable effluent at all times.

A water supply is not built for a few years, or for a decade, but for a lifetime, and because there are those who prefer some other system, no matter what the local conditions may be, engineers should not blind their eyes to the importance of giving a fair trial to this method of water purification.

Passing to the question of infiltration galleries proper, there is no good reason why they cannot be designed to maintain a constant flow

Mr. Potter.

and not gradually decrease and ultimately become obsolete, as is generally the case. They should be as dependable as the identical natural process of ground-water seepage into surface streams. An infiltration gallery, to be permanently successful, must never be forced to such an extent as to allow it to be partly emptied. When it is partly empty, high velocities are set up in its vicinity, which, in time, cause the silting up of the filter media immediately surrounding the gallery, which condition slowly but inevitably results in the breaking down of the system.

It is not a difficult matter to regulate the output from a given infiltration gallery so that it cannot exceed a predetermined maximum discharge, and, by so doing, the lowering of the ground-water plane below the top of the gallery can be prevented, which condition will keep entrance velocities within safe limits and thus maintain indefinitely the integrity of the system.

Throughout the country there exist large deposits of sand and gravel which, if intelligently treated, can be counted on to yield large supplies, and there are also sand and gravel deposits in which the depleted water supply can be augmented by the construction of large storage reservoirs over such a system of infiltration galleries. These reservoirs function as feeders to the infiltration galleries constructed within the confines of the subterranean basin.

The maximum rate of downward filtration which can be maintained permanently is still a mooted question. In the Morris Canal, the leakage, after 100 years of service, averages at the present time 1 250 000 gal. per mile, or from about 200 000 to 250 000 gal. per acre per day. A filter gallery constructed parallel and adjacent to the Morris Canal could be counted on to derive indefinitely 1 250 000 gal. per mile per day from the canal proper. Although feasible to draw off water for short periods at higher rates than this, such an attempt might prove disastrous, as rates of leakage in excess of the natural flow might cause the bottom of the canal to silt up, resulting in a possible break-down in the gallery.

The attention of engineers must be devoted more and more to the determination of safe yields from such underground supplies and galleries, and to the method of controlling the draft therefrom to predetermined and safe quantities.

The speaker is in hearty accord with Messrs. Fuller and Fuertes as to the wisdom of changing the present method of determining and reporting *B. coli*. When the warning signal rings just as loudly at the approach of a cow, or a tramp, walking on the railroad track, as it does for the fast moving express train, one is likely to have contempt for the signal or demand its change. When the presence of *B. coli* may mean evidence of contact with anything, from the human intestine to

the covering of a kernel of wheat, one of two things must necessarily happen: contempt for the warning, or unnecessary and unwarranted alarm. It is difficult to say which is the more damaging. Mr. Potter.

This unnecessary alarm is exhibiting itself in the laws proposed for enaction in certain of the State legislatures. Certain legislation existing or proposed in many of the States indicates clearly that the authors or the sponsors for such legislation lack the fundamental principles of sanitary science. These laws seek to prevent the entry of sewage, either crude or purified, into the waters of the State. Such a bill is now before the New Jersey Legislature, submitted under the very attractive title, "An Act to Prevent the Pollution of Sources of Potable Water Supply in This State." The principal provision is contained in Paragraph 2, which reads as follows:

"2. It shall be unlawful for any person or persons, private or municipal corporation, to discharge into any water which may constitute or form part of a source of potable water supply any raw or treated sewage, or the effluent from any sewage disposal works, after the date fixed by the State Board of Health when such acts shall cease. Notice to discontinue the depositing of such sewage or effluent shall be given by the State Board of Health to such person, or private or municipal corporation, at least three months before the date fixed by said State Board of Health as aforesaid."

Other provisions of the Act leave the State Board of Health no alternative but to enforce the law prohibiting the discharge of the effluent of any sewage disposal plant, no matter what its degree of purity may be.

Another bill, almost as drastic, has been made a law by the State Legislature of Texas, and, in Oklahoma, the Health Officer, 6 years ago, laid down the principle that neither crude sewage nor purified sewage would be permitted to enter the streams of the State. Even New York State is now seriously contemplating the abandonment of hundreds of thousands of dollars spent on new public institutions, because the authorities feel that they cannot even trust the engineer to design a plant which will insure the conveying of the effluent by pumping from an efficiently designed sewage disposal plant outside of the water-shed of a portion of New York City's water supply.

This idea, which is gaining momentum, carried to its absurd but logical conclusion, means that no city in the United States can discharge its sewage into any body of water which is not tide-water. It is the speaker's opinion that the matter is sufficiently important to demand the serious thought of this Society, and he would suggest that the attention of the Board of Direction be especially directed to this matter, to the end that some intelligent measures may be taken by the Society to counteract this dangerous proposition.

Mr. Fuller

GEORGE W. FULLER,* M. AM. SOC. C. E.—This is quite an unusual paper. It deals with local politics and personalities, exploits some of the general features of the laws of hydraulics pertaining to underground water supplies, and closes with a description of a filtration project which is unique.

In association with James W. Fuertes, M. Am. Soc. C. E., the speaker reported on the situation, after Morris Knowles, M. Am. Soc. C. E., had been called to Parkersburg to advise as to whether a well-water project was feasible, and preferable to filtration of the polluted and impure water of the Ohio River.

Mr. Knowles' general viewpoint was that a well-water project was a fairly feasible one. That report produced some differences of opinion in the community, with the result that a Board of Engineers was appointed to make further investigations.

The speaker agreed with Mr. Fuertes that a mechanical filtration system was to be preferred to a well-water system. Whatever merit there may be in the Fuertes and Fuller report is not in the detailed results set forth in the paper, but rather in the careful application of the fundamental principles involved.

Effort was made to explain, as engineers, to a community that had its well-defined factions, the underlying principles involved. In outline, the fundamental propositions involved are: first, that, for an adequate underground water supply, it is necessary to determine whether or not there are sufficient porous water-bearing strata; second, where does the water come from, which supplies the strata; third, where, under present conditions, does that water go; and, fourth, what is the best way to collect that water for municipal water supply purposes.

Some rather unusual conditions are found above Parkersburg, in that there is a rocky promontory, a few miles above the city, which makes a rock dam across the Ohio River. Consequently, there is no large flow of water in this vicinity beneath the bed of the river. The old river-bed undoubtedly swung to the south, against the West Virginia foot-hills. The surface water from those impervious hills came out above an impervious stratum at the surface of the bottom-lands, and found its way into the river, not through the underground porous strata, but as a surface stream flowing over the impervious clay and silt directly to the river.

Then, it was found necessary to reckon with a partial flow from a very limited drainage area of the river plain, or bottom-lands, plus the underground flow of water to the wells from the adjacent Ohio River. The various hydrographs in the paper show some rather unusual conditions. They show in this river plain a very marked rela-

* New York City.

tion between the widely fluctuating water level of the river and the water level in the deep gravel strata into which the wells were driven. Mr. Fuller.

The obvious deduction was that during high river stages there was plenty of water which would flow to wells that might be sunk in the bottom-lands near the river. When the river level was very low, there was not only a gradually receding water-table in the bottom-lands, with the water from the land side making its exit into the river, but there was also the very striking difficulty of having only small volumes of river water flowing back in a reverse direction from the river to the system of wells.

That small increment of naturally filtered river water in the gravel strata was due, of course, to the blanket of silt and clay which formed on the bottom and sides of the Ohio, at times when the flow down the river was insufficient to produce a scouring velocity to push it away.

The ground-water proposition was abandoned for the reason that there was not water in ample quantities coming from the land side, and, as to that coming from the river side, it was very uncertain whether at times of low water the blanket or carpet of clogging materials on the river-bed could be disturbed so as surely to allow water to reach those wells. Mechanical filters were recommended.

S. M. Gray, M. Am. Soc. C. E., was called in to review this proposition, after an injunction suit precluded carrying out the recommendations of the Fuertes and Fuller report. Mr. Gray recommended a project which, although it may have been adopted in certain respects in other communities, was new in its entirety, as far as the speaker knows, in a city of this size. The Smith system appears to be essentially an old-fashioned slow sand filter layout, without any impervious concrete bottom, without any concrete walls, and with reliance placed on two things to maintain the supply during the very varying stages of the Ohio River, ranging from about 5 to 60 ft., from minimum to maximum, in a cycle of a few months.

During the high stages, the velocity of the flow is so great as to scour away the silt deposits on the surface of the sand bed. To maintain quality and quantity of output at times of low river stages, when there is not a scouring velocity for the removal of surface deposits, Mr. Gray has endorsed, and there has actually been built at Parkersburg, a project with some of the earmarks of a mechanical filter. It has a pipe system scattered over the bottom of $1\frac{3}{4}$ acres of sand resting on gravel of one grade, and, at intervals, it is proposed to back-flush one-fifth of that area, or $\frac{1}{5}$ acre; and on that $\frac{1}{5}$ acre, it is proposed to use about 40 000 gal. during an interval of 15 or 20 min. to remove these clogging materials.

From the standpoint of hydraulics, the speaker is a little disappointed that we have not obtained from Mr. Gray or his assistant, Mr.

Mr. Fuller.

Leland, some of the details with respect to that proposition. It brings up several queries: In the first place, as regards cleaning mechanical filters, the fundamentals are, in a rough way, that the summation of exit area of the orifices through which filtered water has to pass should be less than the area of the distributing pipe. Otherwise, the proper pressure is not obtained to force water through every orifice throughout that area, so as to lift and wash the sand thoroughly, say, with a vertical rise of wash-water of from 8 to 12 in. per min. At Parkersburg, the sand is not cleaned so uniformly, but the facts as to distribution of wash-water are not made plain.

Of course, it must be recognized that this is not a proposition directly comparable with a mechanical filter, where wash-water is sent at high velocity through a strainer system under every square foot of filter bed in order to give a thorough cleaning. This Smith system seems to be one of those arrangements where back-flushing is used simply to lift the clogging material sufficiently so that whatever flow there may be in the river may be sufficient to move that material beyond this area.

Slow sand filters are back-filled, of course, very slowly, in order to remove air, and Kirkwood's book on filtration states that, more than 50 years ago, such a filter at Tours, France, was cleaned by back-flushing. However, it is stated by Kirkwood* that the head of water was insufficient and the process was not successful.

To build this filtration system of 1¾ acres at Parkersburg has cost $80 000. That is a somewhat larger sum than was spent at Lawrence, Mass., for building in 1893 an open filtration plant extending over 2½ acres. The speaker does not recall what Mr. Fuertes and he reported with respect to the cost of mechanical filters at Parkersburg, but is inclined to think that it was markedly less than that of the Smith system.

Speaking about costs, mention should be made of one point that is set forth on page 752 of the paper, where it is stated:

"It is gratifying to note that the new pumping equipment has effected an economy sufficient to pay the capital charges on the bond issue required by the new plant."

As a citizen of Parkersburg and a member of the Water Board, Mr. Hall is entitled to a great deal of commendation if he is able to establish a new and reliable plant without any added cost to the tax-payers; and the low operating expense of the Smith system is certainly one of its strongest points.

This Smith system, which is understood to be patented, has not been exploited at many other places. At Henderson, Ky., it was reported on by Philip Burgess, M. Am. Soc. C. E., and found to have

* Pp. 125–126.

some local merit. George A. Johnson, M. Am. Soc. C. E., and his associates at Wheeling, W. Va., reported on it at great length, with unfavorable conclusions. Mr. Fuller.

It is interesting that, within the past 6 months, Mr. Leland has overhauled the sand and gravel, in connection with back-flushing, rather early in the period of drought in 1916.

With regard to quality, the water furnished by the Smith system is generally of good appearance. In point of hardness, it does not vary markedly from that of the Ohio River. In that respect, it compares with what would be produced by a filter plant of any kind.

With regard to the bacteriological aspect of the water, it is doubtful whether it is of as good a quality as would be afforded by any of the so-called standard modern filter systems or as good a water as the people of Parkersburg ought to obtain. It is rather doubtful whether this water supply is able to comply with the standards of the United States Government, as set forth by the United States Public Health Service, a branch of the Treasury Department, *viz.*, not more than 2 *B. coli* per 100 cu. cm.

That Department has provided certain tests for intestinal bacteria in waters supplied to Interstate carriers. Looking over the analyses on page 786, it is doubtful whether the City of Parkersburg could sell water to the railroads which pass through it and not get into trouble, if there should be a thorough analytical study of the water.

In making that comment, it is only fair to state that this is a wonderfully transitional age, in point of water quality. Many cities are supplying water of the highest type in point of quality, either by filtration or by the elimination of sources of pollution. By this means the typhoid death rates of American cities have been reduced to a point which seemed almost inconceivable 10 or even 5 years ago. We have death rates to-day, in cities supplied with filtered surface water, which are as low as those found in European cities, in Holland, and in certain Rhenish districts, where they have pure water from underground sources.

There is, however, a very anomalous situation prevailing in America to-day, in that in some of the surface water supplies there seem to be bacteria of many different kinds, which are classed by laboratory men as members of the *B. coli* group. Some of them are said to be the sour milk bacteria—whatever that may be. Others are said to be bacteria which grow on grain and are found in soils.

In certain districts, where there is a purely rural population, with here and there a scattered village, it is said that there are water supplies which are so polluted, according to laboratory evidence, that they could not reasonably meet the Government standards, even after filtration.

Mr. Fuller.

In relation to this matter, it may be stated that there will be published within the next few weeks a new edition of the so-called "Standard Methods of Water Analysis" (American Public Health Association), the purpose of which is to separate some of these forms of bacteria from the so-called *Bacillus coli*. Just where it will lead is not known, but the situation to-day, in point of quality of water supply for American cities, is a very anomalous one. It is not readily known whether any given city is living up to the legal requirements of the Federal Government; and, if it is not, it is not known whether the apparent fault is genuinely attributable to sewage pollution, whether it is due to laboratory caprices in reference to the sour milk bacteria, whether it is due to harmless bacteria that grow on grain, or whether it is the fault of the handling of water by filtration, or otherwise.

It is hoped that the next year or so will see a sharp turn in the road, a change from the uncertainty of the past to a definiteness of assignment between cause and effect, so that there surely will continue the improvement in quality which is one of the striking features of the past generation in the point of municipal water supply.

The speaker is glad that the author has presented this paper. It sets forth some simple truths which could be considered to advantage by all who are interested in the subject. He has not been very prolific in setting out the specific details of the Smith system, and it is to be hoped that more data may be obtained later.

Mr. Potter's remarks bring up a question that is very active in the interpretation of the treaty passed in 1912 between the United States and Great Britain, with respect to controlling the pollution of boundary waters. There has been under discussion now for about 3 or 4 years the wording of a procedure to stipulate plainly what shall be the quality of the boundary waters, so that life or property on one side of the boundary shall not be affected prejudicially by those who discharge sewage into these waters on the other side. After the many efforts made by the Canadian and United States Governments to solve that question, it would be better to wait until we get further evidence from those who are at present studying it.

With regard to Mr. Potter's remarks on the so-called intestinal bacteria, some men want to exploit water analyses very quickly in laboratories, where the results are to be used by the men responsible for the management of a filter plant, or by those who direct the endeavors of a large number of inspectors on a water-shed. Presumptive tests are not well thought of by those who desire to form an opinion on the intrinsic merit of the sanitary quality of water, and especially in the comparison of different waters. For the past 10 or 20 years there have been growing up two factions with respect to

applying laboratory methods to the control of water supplies. The men in one set want to get results in 24 hours. They have had their way for the last 5 or 10 years. They have brought into municipal water reports, during the last few years, a set of results which have helped the filter operator, but, to the men who have given years in attempting to control water pollution, these results are open to grave suspicion and are exceedingly difficult, if not impossible, of interpretation. Mr. Fuller.

On considering these figures in type in a municipal report, without any personal knowledge of the environment to which these data apply, trouble ensues. Some of these bacteria, classed as *B. coli,* innocent as they may be, may multiply and breed in water under certain temperatures. This certainly adds to the complications. There ought to be a marked change with respect to laboratory data for the sanitary control of the quality of water supplies in America. Engineers must recognize two distinct phases, one, the quick result to help the filter operators and the men who direct inspectors. When it is desired to get a measure of sanitary quality, however, it is necessary to go deeper and further, and to take 8 or 9 days for analysis, something which the filter operator will not tolerate. On the proposition of telling whether or not a water will measure up to prescribed sanitary requirements, it seems highly important to make every effort to separate fecal from non-fecal bacteria in the laboratory.

Nicholas S. Hill, Jr.,* M. Am. Soc. C. E.—Mr. John W. Hill and Mr. Fuller have covered this paper so thoroughly that it leaves very little to be said in the way of discussion. The speaker certainly agrees with both of them in their criticism of the Parkersburg system. Mr. N. S. Hill, Jr.

The situation in Parkersburg recalls a condition that so often exists, and the futility of expert reports under certain conditions, that is, the natural tendency of people to adopt a so-called pure underground water supply, with all its uncertainties as to quantity, rather than the acceptance of a surface water supply of known abundance, treated with modern processes which have a known efficiency.

The use of underground waters is not without dangers; and, without discussing this paper in detail, it might be well to call attention to a situation which sometimes arises where underground water supplies are developed. The speaker alludes more particularly to the East Orange water supply in New Jersey, and will refer to the case of Harper *versus* the Mountain Water Company. This case was tried at Somerville, N. J., before the Hon. William J. Magie, then Chief Justice.† The following is a passage from the Judge's charge:

* New York City.

† A convenient summary of this case, by Vice-Chancellor Emery, may be found in 20 Dickinson, p. 479.

Mr. N. S. Hill, Jr.

"I think I should first give you what the law defines as the rights of parties respecting water running in streams. Any one owning on the banks of a stream of running water is entitled by law to have the waters of the stream come down to him in their natural flow, uncontaminated, unreduced, and unobstructed, except so far as Nature affects them. Persons owning above the line of the person who has these rights have also rights in the water passing them, and their right is to have the water pass them and go down to those below unaffected by obstruction from below or unaffected by obstruction or abstraction from above; each of these parties has a right to the use of the water, which is a reasonable use of the water as it passes. Water may be thus used for irrigation, for the watering of cattle, for the use of water around buildings and houses, for the use of water to produce power and thereby run mills or whatever else power may be applied to. I say the riparian owner, that is, the owner on the bank of the stream, has the right, the right to water coming down from above unobstructed, unpolluted, and in its natural flow."

The same rule has been applied to a clear case of a subterranean stream, and apparently no distinction is drawn, whether the underground water is regarded as percolating water or water of a well-defined subterranean stream.

Vice-Chancellor Magie proceeded to say that though a person or company might strike underground streams and abstract underground water which "might" come to the surface, and might carry this percolating water off and sell it, yet, if by their works they abstracted the water or reduced the level of springs or streams which "had" come to the surface, it was an actionable wrong. The words "might" and "had" in this case are emphatic. The jury was directed that, if it was shown by a preponderance of evidence that the defendant had abstracted an appreciable quantity of water which "had" come to the surface in a pond, spring, or stream, so as to diminish the flow, and had done this either by pumping from the stream or from a well, or by both, then the plaintiffs were entitled to damages.

Later, there has been the decision in the case of Frank Meeker *versus* the Mayor and City Council of East Orange. The City of East Orange recently established an underground water supply, deriving its water through wells about 150 ft. deep. The plaintiff stated that, before and at the time of the establishment of wells, he owned certain property and lands in Millburn and Livingston, having an area of about 100 acres, that by reason thereof he was entitled to the benefit and advantage of a certain spring and stream running and flowing into and through those lands, and that the defendants, by Artesian wells, pumps, and reservoirs, did, between January 19th, 1905, and September 25th, 1906, divert large quantities of water from said springs and streams, to the prejudice of the plaintiff.

Mr. N. S. Hill, Jr.

Judge Adams, before whom the case was tried, charged the jury as follows:

"If you are satisfied that if, by the operation of the defendants' works in intercepting underground waters, any existing natural surface stream was diminished in its flow on the land of Mr. Meeker to an appreciable extent, he has suffered an actionable wrong, and is entitled to compensation."

Furthermore, he stated that the alleged diminution of the surface streams and the alleged destruction of the run-off from the springs are claims independent of one another, but covered by the same legal principle. He referred to the Harper decision, and stated:

"It is not easy to determine just what inferences are legitimate from the language used by His Honor, Chief Justice Magie, in dealing with a case similar to this and yet not altogether analogous. On the whole, I conclude that the Harper case warrants this Court in saying that when an existing spring, actual, not merely potential; visible, not occult; a spring, not a well; brought to the surface by natural force, not conducted there by the labor of man—when such a spring is depleted by subterranean suction occasioned by the operation of a pumping plant like that at East Orange, an actionable injury is inflicted upon the owner of the land on which the spring is situated, for which the law will award sufficient compensation."

In another case, Smith *versus* the City of Brooklyn (160 New York, page 357), the following principle was laid down. If a city, by the operation of a water system, consisting of wells and pumps on its own land, drains the contiguous territory, and thus diverts and diminishes the flow of water in a natural surface stream on the land of another, it is answerable in damages, under the law that no one may divert or obstruct the natural flow of a stream for his own benefit to the injury of another.

Under these decisions, no provision whatever has been made for the assessment of permanent damages. A man brings an action for the damages resulting from the diversion of underground waters for a definite period, and asks to be reimbursed for the damage which he has suffered during that period. With surface streams the damages awarded are permanent, and the Courts have defined their measure as the difference in the value of the property before and after diversion. The result of these decisions has been that East Orange has been in constant litigation since 1905, when its underground system of water supply was started, and the City has been compelled to acquire by condemnation more than 1 750 acres of land for which it has no specific use, in order to prevent continuing damages from accruing from year to year. This property has cost the city $400 000 more than the original estimate for the water supply system, or approximately 25% of its value.

Mr. N. S. Hill, Jr.

There are many situations in which such a condition may develop, and every engineer should use great caution in advising a municipality to embark in an underground water supply before satisfying himself that such a condition is not likely to arise.

The speaker simply calls attention to this added element of uncertainty, in conjunction with consideration of this paper. It is not always possible to develop underground water supplies and be entirely free from claims for damages to surrounding property, as many suppose.

Mr. Spear.

WALTER E. SPEAR,* M. AM. SOC. C. E.—It would be pertinent to the discussion of this paper to speak of two of the larger German ground-water works which derive at times a large portion of their supply from adjacent streams in somewhat the same manner as the Parkersburg works. The collecting works of the first of the two large ground-water plants supplying Dresden—the Saloppe Works—with which many members of the Society are doubtless familiar, consist of a slotted cast-iron pipe, about 4 700 ft. long, and from 18 to 26 in. in diameter, which is laid along a low bank of the river about 50 ft. from the edge of the water at ordinary low stages in the Elbe, and about 8 ft. below the river surface. The cover of sand and gravel over the gallery is about 15 ft. The maximum yield of this water in 1904 was given as 12 000 000 gal. per day. Originally, it was believed that all the water obtained at this plant represented the ground-water flow from the upland water-shed that came slowly through the gravel strata in the broad river valley. This idea, however, was soon abandoned. At high river stages, when the ground over the gallery was flooded, it was found that very considerable quantities of water came directly from the river through the 15 ft. of cover. Ordinarily, the water from this gallery was of very good quality, but, when the river was in flood, and a large proportion of the supply was filtered river water, it showed some deterioration. During a flood in 1896, when the river was 10 ft. above the surface of the ground over the gallery, there were several thousand bacteria per cubic centimeter in the water delivered at the station. There was no typhoid fever in Dresden as a result of the flood, but many cases of intestinal disorders were reported in the city.

The Schierstein Works, supplying Wiesbaden, at the time of the speaker's visit in 1904, drew a supply of water from 32 wells driven along the Rhine at a distance of from 200 to 400 ft. from the water at low river stages. These wells were about 35 ft. deep, and penetrated a thick stratum of sand and gravel, which was covered for the most part with a layer of sandy clay 10 ft. or more in thickness. Ordinarily, the supply from these wells was of good quality. It was practically all ground-water, but the cover of sandy clay was known to be absent

* New York City.

in the river channels, and the director of the works, Mr. Halbertsma, considered it wise to put in an ozone plant at the works to sterilize the water when the Rhine was in flood. Mr. Spear.

In looking over the description of the Parkersburg collecting works and noting the meager thickness of cover over the screen sections, it would seem to be the part of prudence for those responsible for their operation to put in a sterilization plant. Although such a plant might well be operated all the time, it should certainly be used when the river is in flood, when the surface of the filter, therefore, is inaccessible, and when the analysis of the water shows signs of pollution.

The Parkersburg plant has some slight resemblance to artificial ground-water works constructed extensively in Sweden, where there are natural beds of sand and gravel, as at Parkersburg, without any adequate supply of ground-water. At these works in Sweden surface water is applied through open channels to the surface of these beds of pervious material, and the water filtering through is abstracted below, generally from wells driven at a safe distance from the open channels. The surfaces of these beds may be cleaned like a filter, by cutting off the supply and allowing the water to drain away. In respect to the depth of material through which the water flows to the wells, and the readiness with which the filter surface may be cleaned, these Swedish works differ from the Parkersburg plant, and these points of difference seem to constitute the chief elements of weakness in that plant.

T. Kennard Thomson,* M. Am. Soc. C. E.—This paper is of special interest to the speaker because he has long had a high opinion of the author, a graduate of West Point, and has himself had considerable experience in, on, and with the Ohio River, first at Kenova, about 125 miles south of Parkersburg, where the depth was 6 ft. at low water and 66 ft. at high water, with very sudden fluctuations or floods; then at Mingo Junction, about 75 miles above Parkersburg. Mr. Thomson.

The speaker also designed caissons for the Wabash Bridge over the Monongahela River at Pittsburgh, just above the junction of the Monongahela and Alleghany, about 200 miles above Parkersburg.

Mr. Fuller has mentioned the impurities of the Ohio River water, and his reference can readily be understood by any one who knows the river. In the first place, to give some faint idea of the sediment carried by this river, it might be stated that, during the winter of 1890-91, one of the coffer-dams for the Kenova Bridge, which was approximately 30 by 100 ft. and 25 ft. in depth, was left in the river. When the waters subsided in the spring this coffer-dam was found to be filled to the brim with sediment. The speaker has no means of knowing whether or not the river could have filled it more than once during the winter.

* New York City.

Mr. Thomson.

A river which carries such an immense quantity of sediment and is subject to such severe floods and dry spells is not very dependable, to say the least. To make matters worse, the river is not only polluted by the discharge from many sewers, but, also, during these periodical floods, by the water washing and receding from the streets, cellars, houses, stables, barnyards, chicken coops, etc., of many towns and cities, Pittsburgh included. In fact, one would imagine that the water would be much better for fertilizing crops than as a domestic supply.

The speaker thinks the Parkersburg authorities were wise not to try to pump 3 000 000 or 4 000 000 gal. of water a day from fourteen wells placed some distance from the shore; for he does not think it possible to pump such a volume of water continuously without removing more or less sand, perhaps in almost imperceptible quantities, but still sufficient to form cavities.

These cavities would probably cause no damage in the open fields, but, sooner or later, these fields will be built on by the city; and though the subterranean cavities might even then give no trouble for many years, they might sometime, suddenly, cause very serious collapses, similar to those which have happened to cities built over coal mines. The experience gained by Parkersburg through its adopted plan would seem to prove the correctness of this assertion.

Some day all the towns along the Ohio (and this applies also to other rivers) will combine to dam the water up in the mountains, where it is comparatively pure and free from sediment, and pipe it to the different towns as needed. This will not only give an adequate and dependable supply of good water, but will also regulate the flow in the rivers, doing away with the disastrous floods of periodical occurrence. As an example of many towns along the Ohio: when the speaker first saw Catletsburg, Ky., the town stood on a bluff some 20 ft. above the river. The next spring he saw rowboats landing at the second-story windows of the houses. These floods occur so quickly that, even with the excellent modern Weather Bureau service, the inhabitants do not always have time to protect their property; yet they come back, clean their houses, make the best of their losses, and start over again; they very seldom move away or build on high ground.

The Court decisions quoted by Mr. Hill would seem to indicate that the small towns may some day be able to force the towns above them to provide pure water or to stop polluting the rivers.

Mr. Dunham.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—A paragraph on page 780 giving the dimensions of the intake pipe could be illuminated by mention of the connections to, and the character of, the pumping machinery. It would appear from the text that the large diameters of the intake or "suction pipe" were expected to lessen the otherwise

* New York City.

"undesirably rapid rate" of flow through the filtering material. This implies the use of intake pipes as reservoirs from which a certain quantity of water could be taken without marked or legitimate effect at the strainers. Is this view correct? Ordinary experience would tend to show quite the reverse; that the friction losses would be less and the draft at the wells greater with large pipes under a vacuum produced by pumps of any description. Mr. Dunham.

Strainers with V-shaped openings have been used by the writer, not always in vertical positions, but always at some angle and with connections that would allow of access to each well or to each one in a small group when shut off from the others in a system. Any other method seems to be open to distrust, although it is true that conditions vary greatly, and each case is a problem by itself.

Many years ago, the writer examined sand bars in the Ohio River in the vicinity of Wheeling, W. Va., for the Wheeling Water Board, but found little encouragement in quality or volume, although the beds were continuous to a depth of 40 ft. below low-water levels. Besides hardness, the figures for iron were too high, and filters were recommended.

THEODORE S. JOHNSON,* ASSOC. M. AM. SOC. C. E. (by letter).—In reviewing the problem of water supply, the same questions that arise at the beginning of the study are still to be considered after some one solution is adopted; namely, is the water obtained of satisfactory quality from chemical, physical, and bacteriological standpoints, and, is the requisite quality obtainable at a fair cost of production? Usually, these questions can be answered after some investigation. It is to be regretted that rarely are two solutions of a water supply problem provided so that they may be compared in actual performance under the same conditions of demand and production and at the same time. In this discussion the operation of one type of supply is presented, and an attempt is made to compare it in results with one not in operation. This is a handicap in solving the problem as to the scheme which has not been adopted. Mr. Johnson.

This paper recites the preliminary investigation for a well supply for Parkersburg, and then describes the construction and operation of a system not capable of such preliminary investigation, concerning which little or no previous research or study had been made. It would have been desirable to have answered in the paper the following questions:

1.—How does the present supply compare, in turbidity, total hardness, iron and bacterial content, in color, and in other factors affecting the desirability of a water supply, with the same factors and qualities of the water taken from the well supply as investigated

* Granville, Ohio.

Mr. Johnson.

by Mr. Knowles and by Messrs. Fuertes and Fuller, which supply was rejected?

2.—How does the cost of pumping from the present beds compare with the estimated cost of pumping from the line of wells? Speaking more generally, how does the cost of operation, including capital charges, compare with the same cost as estimated for the rejected supply?

3.—What may be the probable life of the present plant, as compared with that of the plant for well pumping? The object of this question would be to show the effect of depreciation and maintenance charges on the cost of pumping.

The data in the paper are not sufficient to enable the reader to determine the answer to the first of these questions. The reports published in the paper, showing turbidity, alkalinity, and total hardness, are given only for one month, and therefore cannot be regarded as showing very fully the characteristics of the new supply. The figures in the table on page 785 are interesting. For example, the iron content of the raw river water varies from 1.06 parts per million, on January 20th, to 7.04 parts per million on January 24th, 1914. This is a very wide range for iron content in the raw river water in such a short period. Again, the average iron content for the month is 3.33 parts per million. Having been familiar with the untreated Ohio River water from his earliest remembrance, and being at present a user of water in which the iron content is slightly more than 1 part per million, the writer is surprised to find the Ohio River water so contaminated with iron. He is still more surprised to find, on page 783, a report of an investigation of the supply by Mr. I. L. Birner, which states: "The total iron in solution, of the filtered water, was 0.19 of one part per million, against an average of 5 to 16 parts in the river." From the wording of Mr. Birner's report, one is led to believe that he refers to parts per million, and this would seem to indicate a river water extremely polluted with iron. The only data which the writer has immediately at hand are those given in the Report of the Ohio State Board of Health for 1908, on page 206, where results are given for tests made at Marietta, Ohio, a few miles up stream from the site of the present filtration works. These tests show an average iron content for 1906 of 0.62 part per million, and the maxima for the year are found to be 1.00 and 1.23 parts per million for August and November, respectively. It is difficult to reconcile these two statements.

In the same report the bacterial results show the untreated water at Parkersburg to have from 100 to 3 100 bacteria per cu. cm., and the filtered water from 24 to 1, with averages for the month of 900 and 9.3 for the untreated and filtered waters, respectively. Tests

Mr. Johnson.

by the State Board of Health at Marietta show that the average of a large number of determinations indicates a bacterial count of 8 200 per cu. cm. in the raw water during 1906, and 7 350 during 1907. The same investigators, in tests made on July 24th, 1906, at Pomeroy, Ohio, show 19 100 bacteria per cu. cm. in the raw river water and 8 200 on November 19th, 1906. Although these are only scattered results of tests, they serve to cast some comparative light on the published figures. That the safe condition of the water, as indicated by the tests of Dr. Rose and Mr. Birner, is not generally recognized, is shown by the suggestion that a report prepared by the City of Wheeling and tests by the State Bacteriologist of West Virginia both agree that at times the water is quite unsafe.

Engineers may then reasonably inquire whether experience with other well supplies, or tests on the wells as driven at Parkersburg, would not indicate that the quality of the water from the well supply is better than that furnished by the present infiltration system. If there are published or available reports on the well supply, or additional tests on the present supply, which will throw more light on this question, it would seem highly desirable to have them published.

To answer the second question—how does the cost of pumping from the present beds compare with the estimated cost of pumping from the line of wells?—the necessary information is not available in the paper and, by all means, should be presented by the author or by the engineers concerned. The figures on page 781, showing the cost to be $11.03 per million gallons, are very evidently only for the cost of operation, and include no capital or depreciation charges. The data on pages 780 and 781 do not separate items in construction cost in such a way that direct comparisons can be made.

The service life of the present plant is necessarily one of doubt. It is not the time in which the present construction will furnish the proper capacity, with which we are concerned, but rather the life of any one filter unit. Relative to this it is noted that an examination of the beds in 1916 showed that, at several places, there were holes in the sand and gravel covering. These holes were from 5 to 10 ft. in diameter, and were formed like craters, extending to within 1 or 2 ft. of the brass strainer pipes. The writer has been long familiar with the locality in which the filter beds have been placed, and was engaged on some surveying work, in connection with the quantities of excavation under the contract, at a time very near that at which the photograph shown in Fig. 13 was taken. At that time, he was able to walk to the coffer across the slightly raised level of the bar, and, on every side, were to be seen similar crater-like holes in the natural surface of the sand-bar. In some of these there were pools of water in which children were bathing. It has been the writer's

Mr. Johnson.

opinion that if these craters would form in the natural bed, they would be as likely to occur over the filter bed, and, if so, would of course greatly impair its efficiency. Though these holes may be refilled, it would seem hardly possible to conduct the refilling so as to secure uniform stratification in the bed, and the reasonable life of the infiltration plant would be considerably shortened by this cause alone. The efficient life of a rapid sand filter or a slow sand filter is a question which can be answered with fair accuracy. It would not seem that the conditions providing stability in the plant were to be found in the shifting variable sand bottom of the Ohio River.

In a general way, the comparison of this plant with either a filtered water supply from the Ohio River or a supply drawn from wells in the gravel beds of the adjacent bottom-lands can be put on a satisfactory basis only when the Smith infiltration system is regarded as being of the caisson type or as a type of sand filter. If of the latter type, it would seem that the same conditions which have been regarded as necessary to secure a satisfactory supply from a rapid sand or slow sand filter would have to be applied to the Smith system. Among the first requisites for either of the usual filter types is a careful control of the operating head, as affecting the rate of filtration, and both types are considered as sensitive to small changes in the effective heads. With a range of 53.1 ft. in the stage of the river, it would hardly seem probable that the filtering conditions remain the same.

Another requisite of proper sand filtration is a careful control of the cleaning processes. The filters are constantly inspected and watched, and the conditions carefully maintained for securing equal fitnesses and thorough washing of all their parts. If the beds of the Smith system are pitted with crater-like holes extending to within a short distance of the strainer pipes, the efficiency of the back-flushing would certainly be reduced. If, as a matter of experience, such back-flushing does cleanse all parts of the filter bed very thoroughly and uniformly, the data which prove this fact would be interesting.

With a supply of extremely varying nature, such as that found in the Ohio River, sand filtration plants are accustomed to have constant and rigorous tests at least daily, and often more frequently, on the basis of which the rate and character of their operation is altered. Although the author recommends systematic tests, these tests will be lessened in value by the fact that little or no change could be made in the operating conditions of the filter system. It may then be concluded, in the writer's opinion, that the Smith infiltration system may not be regarded as a purification plant, capable of providing at all times a safe and wholesome supply of water such as is obtainable from rapid sand filtration plants, and, therefore, must be considered

as an underground caisson or ground-water collection system, of rather high construction cost, drawing water either from the river above or the ground-water below, and confining its purification processes to mere straining. Mr. Johnson.

PHILIP BURGESS,* M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest. As stated in the paper, it has been the author's purpose principally to discuss the investigations made by the engineers who were retained by the City to determine the best method of obtaining a satisfactory water supply. The writer was retained by Mr. Smith, the contractor for the system which was finally built, principally to conduct the preliminary investigations which Mr. Smith had made before the construction of the plant, and, finally, to prepare the plans from which the system was actually constructed. The following discussion is offered principally for the purpose of describing the preliminary tests and reports made prior to actual construction. Mr. Burgess.

From his position as an outsider, the writer was particularly interested in the opinions of the comparatively large number of engineers obtained before the City authorities finally agreed as to the system which was considered best adapted to serve the needs of the city. The writer was led to believe that perhaps this condition was attributable largely to the fact that the reports of the engineers as submitted were not sufficiently conclusive and convincing, and that they contained serious differences of opinion.

The first report submitted by Messrs. Chapin and Knowles recommended "that the ultimate object to be looked forward to is the establishing of new water-works at the Camden Farm, with the building of either wells or a mechanical filter plant; the former, if investigations show the feasibility, and the latter, if not so found."

Again, on page 16, of that report, it is stated: "It cannot be too strongly urged that, while the well proposition is attractive, further investigations should be made, perhaps in other localities nearer the proposed reservoir site."

It is apparent that, although this report seemed to favor the construction of a well system, it showed that the engineers were not in a position to make a definite recommendation for building such a system without further investigations.

Under date of February 21st, 1910, Messrs. James H. Fuertes and George W. Fuller submitted to the city officials a joint report, in which appears the following statement:

"We find, as will be seen from the estimates of cost of construction and operation, that a first-class well system and a first-class filter system at the Camden Farm are substantially on a parity as to the quality

* Columbus, Ohio.

Mr. Burgess.

of the water, and as to cost, both of construction and of operation (when a suitable charge for the required land is made against the well system), and that either plant could be depended upon to supply such quantity of water as would be needed by the city for some years. * * *."

The conclusions and recommendations of Messrs. Fuertes and Fuller were very definite, but an examination of their report indicates that these conclusions and recommendations were based on certain assumptions, as shown on page 13 of that report, as follows:

"During wet weather, perhaps when the water in the Ohio River is high, it appears to us that the source of water contained in the pores of the extensive sand and gravel layers is largely river water, but to some extent water from upland sources, the high river stage damming up some of the upland water.

"We are firmly of the opinion that, during low-water stages in the Ohio River, the water which can be drawn from the strata is that which has been stored within the pores of the material at times of previous high water in the river. As this stored water is removed, or naturally flows away, we are certain that, during low stages in the river, whatever water enters these sub-surface strata of sand and gravel is largely of river origin.

"Our conclusion, therefore, is that, as a source of supply for a municipality, the water from the underground sources in question, at the end of protracted droughts, must come from the Ohio River through the bottom or sides of the present river bed along the stretch of the bottom lands below Briscoe."

The conclusions of the engineers as to the source of the gravel-water modified their report, as will be shown in the following discussion. On pages 14 and 15 of the report appear the following statements:

"In the first place, it was found that the water in the porous sand and gravel layers in question did not rise to such high levels as found in the river itself. This is true as indicated by readings in test wells almost at the bank of the river; and shows that, even during fairly high velocities in the river, there is still so much mud and silt deposited on the sides and bottom of the river that a considerable head is required to overcome the friction sufficiently to allow the water, in substantial quantities, to pass through this thin and more or less impervious deposit of mud."

This statement is of interest, in view of the fact that the bottom of the Ohio at Parkersburg is always clean and free from deposits of silt.

In their concluding discussion of the quality of the supplies, the engineers stated as follows:

"There are some slight differences in quality of the water from wells and from filters, the principal feature of which would be hardness on account of the wells yielding water coming largely from the Ohio

River at times when it is in flood and fairly soft. We do not attach much importance to this difference because ultimately during low-water periods the well water would also have its source in the Ohio River. So far as quality is concerned, we put waters from filters and from wells in the vicinity of the Camden Farm on a parity. * * *." Mr. Burgess.

In describing the well system and its operation, the engineers recommended the following method of increasing the supply during low-water stages:

"*River Plant.* To insure the removal of mud and silt from the bottom of the river adjacent to the well plant at the latter end of low-water periods, we have considered it prudent to provide for a hydraulic dredge located upon a barge equipped with 25-horse power engines, steam-driven, and which would operate not only the centrifugal pumps for dredging purposes, but also some arrangement for propelling the boat at intervals up and down this distance of 4 000 ft. adjacent to the wells. The suction of these dredges would be specially designed, resting upon a shoe and with the end attached to a special casting, with a view to removing say for a depth of 1 or 2 in. the material over as wide a strip as possible. It is probable that such a general device could be arranged so as to clean the bed of the river for a width of 20 or 25 ft. and for a length of 4 000 ft. in a working day. This would give an available filtering area of roughly two acres. * * *.

"We estimate that the annual cost of operation and maintenance of a 4 000 000-gal. well water project, exclusive of fixed charges, would be as follows:

Fuel, based on gas	$11 680
Pay-roll	4 000
Supplies, repairs, and renewals (average)	4 000
River dredging	3 680
Total	$23 360

"We estimate that the annual cost of operating and maintaining a 4 000 000-gal. filter plant in a first-class manner, and of pumping the water to the distributing reservoir, exclusive of fixed charges, would be as follows:

Fuel, based on gas	$11 000
Pay-roll	6 500
Coagulants	2 500
Supplies, repairs, and renewals (average)	4 000
Total	$24 000"

From these citations, it is apparent that the conclusions of the engineers as to the cost of operation and as to the comparative merits of supplies derived from a filter plant or from a well system were largely influenced by their assumption as to the source of the well water. It was this assumption in regard to the source of the well water and in regard to the method of maintaining and increasing the available well water supply during dry-weather conditions, which was

Mr. Burgess.

not convincing or conclusive to, at least, some of the city officials and members of the Water Commission. If one omits the annual cost of river dredging, estimated at $3 680, from that of operating the well system, it is materially less than that of operating mechanical filters, as determined by the engineers. In other words, omitting such cost of river dredging, and assuming the filtered river supply and well water to be equally satisfactory as to quality, the engineers' conclusions and recommendations for establishing a mechanical filter plant were not warranted.

Messrs. Fuertes and Fuller did not agree with the conclusions of Mr. Clapp, who thought that the ground-water at the wells had its source partly from the sand plain districts and partly from the bottom-lands in the main valley of the Ohio.

As stated by the author, the City finally employed Mr. Samuel M. Gray, who submitted a final report, under date of May 26th, 1910, which was so convincing and conclusive, especially as to the merits of the system advocated by Mr. Smith, that the City soon entered into an agreement with Mr. Smith to build his system.

The author has given a very interesting discussion of the preliminary investigations made at Parkersburg to determine the comparative merits of supplies, obtained either by filtering the Ohio River water or by puting in wells adjacent to the river. However, he does not mention any of the preliminary studies made to determine the feasibility of the Smith system. This feature of the work embraced perhaps a more thorough investigation than was made to determine the merits of the well system. Moreover, it is the writer's belief that the final success of the Smith system at Parkersburg is attributable largely to the thoroughness with which the preliminary tests were conducted to determine, first, the feasibility of putting in such a system, and, finally, to determine the best location for the plant.

Briefly stated, the method of conducting the preliminary tests included the sampling of the underflow of the river, as obtained by driving small well points to depths ranging from 3½ to 5 ft. beneath the surface of the bar. Water was pumped from these well points for such a time as was required to obtain a clear sample which was finally analyzed for the purpose of determining its chemical constituents. It was recognized that two important features must be considered in selecting the location for the system, namely, that the underground water must not contain an excessive quantity of iron, and that it must not be excessively hard, as compared with the river water.

The first preliminary tests were made at Parkersburg on August 6th and 7th, 1909. At this time only four tests were made, at stations extending from about 5 000 ft. to 1 000 ft. above the city pumping station. The results of the analyses of the samples collected at this time are shown in Table 1.

Mr. Burgess.

The analyses indicated considerable differences in the quality of the water beneath the bar at the different stations. At Station 1, which was near the foot of Neals Island and between the two channels of the river, the ground-water was found to be comparatively hard and of high iron content. This was true also at Station 4, which was 1 000 ft. above the city pumping station. At Station 3, the ground-water obtained from beneath the river was softer than the river water and of low iron content. Near this station, on August 8th, a hole, about 15 ft. in diameter, was dredged in the river bar to a depth of 5 ft. and, in this hole, was placed an 8-in. brass strainer, 8 ft. long, in a horizontal position. The strainer pipe was covered with 18 in. of gravel and about 42 in. of sand. Water was pumped from the strainer by a 2-in. centrifugal pump for the purpose of determining the quality of the water collected in the strainer pipe. Representative analyses of the river water and that obtained from the strainer are shown in Table 2.

Mr. Burgess.

In general, the water obtained from the strainer pipe was entirely clear, even when the river water had a turbidity of nearly 2 000 parts per million; moreover, the total hardness of the strainer water was less than that of the river water. It was undoubtedly true that the success of this preliminary test interested a large number of citizens and officials at Parkersburg, and showed them the possibility of obtaining a satisfactory water supply in this manner.

At the request of Mr. Gray, still further tests were made on May 7th, 1910, to determine the quality of the water in the bar beneath the river and the feasibility of obtaining a satisfactory supply from horizontal strainers placed beneath the bed of the river. At this time, also, by means of a dredgeboat, the material composing the bar was excavated and examined thoroughly to determine its characteristics at numerous points in the river.

As was true during the first preliminary tests, considerable differences were noted in the character of the water obtained from beneath the river at different depths beneath the surface of the bar and at different locations in the bar. The results of the analyses of the samples collected at this time are shown in Table 3.

After the City had entered into a contract with Mr. Smith to build his system, still further tests were made by the writer in June and July, 1910, for the purpose of determining the best location. More than seventy-five well tests were made at intervals of about 100 ft. over the river bottom, and a small pile-driver was rigged up on a small flatboat to assist in driving the well points. The sampling stations were located by stadia measurements from a base line on

the bank of the river. By this method of testing, it was learned that the best location for the system proposed was not opposite the Camden Farm, but several thousand feet below this farm at a point where the material composing the river bar was very satisfactory and the underlying water was of low iron content and softer than the river water. Consequently, this location was selected as best adapted for the system.

Further studies of the design of the proposed strainer system indicated the desirability of dividing it into a number of units with independent suction lines, rather than to make only two units, as was contemplated in the original plan. Moreover, on account of the large losses of head which would develop during back-flushing, it was realized that the pumping station should be at the nearest possible point to the strainer system. As shown by the author, the strainer system, as constructed, was composed of five individual units, each connected by separate 18-in. suction lines to the main suction of the pumps, and the latter were near the river bank opposite the center of the strainer system.

It is the writer's belief that two important features of construction have contributed especially to the success of the strainer system, namely, the provision of a deep bed of clean, coarse gravel over the entire area covered by the strainer system, and the reduction in the area of the strainer pipes at their connections to the main distributing pipes to a diameter of 2½ in. The deep gravel layers have increased the capacity of the strainer system materially, and also the reduction in the area of the connections of the strainer pipes has also increased the efficiency of back-flushing the system, by introducing a loss of

Mr. Burgess.

head at this point, thus causing a better distribution of the wash-water.

In view of the possible differences of opinion as to the source, or sources, of the water in the adjacent gravel bed along the Ohio River, and also in the gravel beneath the river, it may be noted, first, that the entire river bottom at Parkersburg is covered to a depth of approximately 18 in. with very hard impervious gravel layers firmly cemented together. In fact, in some places, during the preliminary testing, the gravel layers were so tight that it was found impossible to pump water from the well points after they were driven. This feature is of interest in considering the recommendations contained in one of the preliminary reports to use a hydraulic dredge of such design that it would remove material from the river bar to a depth of 1 or 2 in. Experience in dredging material from the bottom of the Ohio shows that it is impossible to use hydraulic dredges in this river above Portsmouth, Ohio, on account of the compactness of the surface material.

Moreover, some light as to the probable source, or sources, of water obtained at shallow depths from beneath the river may appear from Table 4, showing results of analyses of samples of water collected by the writer at Sistersville, W. Va., on August 1st, 1910.

TABLE 4.—RESULT OF ANALYSES OF SAMPLES OF WATER FROM THE OHIO RIVER AT SISTERSVILLE, W. VA., AUGUST 1ST, 1910.

* Alkalinity, August 3d, 1910, Sample No. 1 = 28; No. 2 = 5; No. 3 = 44.
Samples of ground-water were obtained 4.0 ft. beneath the surface of the bar.

The samples in Table 4 were obtained from the bar at different stations near the center of the river by exactly the same method as that used at Parkersburg, and it is of interest to note that, even at shallow depths beneath the surface of the bar, the ground-water was of remarkably high mineral content. The samples were clear when collected, but in 15 min. they looked like tomato ketchup.

The writer has made a large number of other investigations, along similar lines, to determine the character of the water obtained at shallow depths beneath river bars, principally at Owensboro, Ky., Gallipolis, Ironton, Zanesville, Portsmouth, and Newark, Ohio, and

Mr. Burgess.

Wheeling, W. Va., and, in all cases, the results obtained have been generally similar to those at Parkersburg. The tests have indicated great variations in the quality of the water at different locations and at different depths of sampling. The writer's conclusion is that the underground water, even at shallow depths, is always of very different quality from the river water, especially during low stages of the streams; also, that during low stages it cannot have its source in the river, but must come from adjacent higher territory and flow toward the river.

An interesting feature was developed at Parkersburg where, in some cases, the water obtained from the well points was of very high iron content and contained only 5 parts of incrustants when analyzed by the usual methods. Its alkalinity was 55 parts. Two or three such points were included within the area covered by the strainer system, and excavations disclosed the fact that a log or trunk of an old tree had been deposited and covered within the river bar. Immediately around these logs, for distances of about 10 ft., the surrounding gravel and sand was filled with iron. When the log and iron deposits were removed, the quality of the water obtained from the ground changed, and resembled that flowing from adjacent areas. Its iron content was reduced to about 0.3 part per million, the incrustants increased to about 70 parts, and the alkalinity was reduced to about 40 parts. The writer has no explanation for this phenomenon.

In that part of the report of Messrs. Fuertes and Fuller which discusses the quality of the ground-water obtained from the test wells it is stated that, in some instances, the ground-water contained objectionable quantities of iron "due to the water dissolving iron during the long intervals of standing in contact with the metal;" and, again, that the large quantity of iron in the well water at the steel plant is explained "partly by the flow of water through a long line of pipe." The writer believes that these statements should not go unquestioned, because undoubtedly the high iron content of the ground-water was not attributable to its contact with iron pipes, but the iron was present in the water in the gravel strata. It is significant that the test wells producing water of high iron content were opposite those points in the river where the well point tests indicated that the underground water beneath the river, also, was of high iron content. It is a common popular fallacy to attribute the iron found in some well waters to their contact with the pipes.

Moreover, the writer would question the judgment which dictated placing the wells along the river bank 400 ft. apart. Such a spacing would seem to be too great, and would not make available all the water contained in the gravel strata. Although the water levels in the test wells indicated that the contours were parallel to the river bank, it

Mr. Burgess.

should be noted that these levels were taken during comparatively high stages of the river. It is the writer's opinion that if levels had been taken during low stages, it would have been found that the ground-water table had a different slope, and that the flow of water would have been slightly down stream toward the river bank. This would conform more nearly to the conclusions of Mr. Clapp, as stated in his report.

It is believed that experience at Parkersburg warrants the conclusion that each of the following features is of importance and should be considered in the construction of strainer systems or infiltration plants of this type:

1.—The presence of a permanent bar of sand and gravel of suitable size within a reasonable distance of the pumping station to which the water is to be carried;
2.—The constant submergence of the bar from which the supply is to be obtained;
3.—The velocity of flow in the stream, which velocity must be sufficient to maintain the bar clean and free from silt and other drift;
4.—The depth at which the collecting units are placed with relation to the bottom of the stream; and
5.—The character of the water which is found beneath the bottom of the stream.

Experience at Parkersburg has shown, also, that it is very important that there should be a suitable meter or measuring device on each suction line from each section of the system. Without such meters, it is impossible to operate the different sections of the system at the same rate. Immediately after back-flushing a section, the loss of head is very much decreased, and it is difficult to avoid excessive rates of filtration from the newly washed unit without a suitable meter.

Although this paper was presented primarily with a view of discussing the preliminary investigations by engineers to determine the merits of the various water supplies available at Parkersburg, it may be well to mention briefly the merits of the system actually built. Its obvious advantages are its low cost of operation and its simplicity and ease of operation. The annual cost of operation is only one-half of the estimated cost of a suitable well system or rapid sand filter plant, as discussed in the preliminary reports of the consulting engineers. Moreover, the operation of the plant is accomplished successfully without expert control.

Though it may be true that the results accomplished by the plant are not within certain arbitrary standards adopted by Federal authorities, it is to be noted that the plant was constructed under more severe

guaranties of efficiency than have ever been enforced at any other water purification plant in the United States. Moreover, the plant was accepted on the basis of these guaranties and on the basis of thorough tests of operation by a competent representative of the City. Mr. Burgess.

It is the writer's belief that the City should erect a suitable chlorinating plant as an additional precaution in securing always an entirely satisfactory supply. In doing so, however, it should be recognized that the City is taking no additional precautions other than those now adopted by very nearly all cities which obtain their water supplies from either rapid or slow sand filters. There is no doubt that the results obtained by the present plant are comparable with those from rapid sand filters, and that the cost of operation is so low that it makes the type now in use at Parkersburg of very great advantage to any city where conditions are such as to permit of its satisfactory installation.

JAMES H. FUERTES,* M. AM. SOC. C. E.—Messrs. Fuller, Hill and Potter, having discussed quite fully the principal and more important matters dealt with by Mr. Hall, a few remarks concerning experiences with somewhat similar methods of securing water from river beds may be of interest. Mr. Fuertes.

A number of water companies and cities on the Allegheny and Ohio Rivers in the vicinity of Pittsburgh take water from these rivers by a plan having general features in common with those of the plan adopted at Parkersburg.

About 10 years ago three citizens of Wilkinsburg, Pa., a suburb of Pittsburgh, brought suit against the Pennsylvania Water Company to compel that company to furnish pure water, as required by the terms of its charter. The suit was rather unique, and was one of the few recorded in which a decree has been entered directing a company to secure and provide a sufficient supply of pure and wholesome water. The supply against which complaint was made was drawn from gravel-covered cribs in the Allegheny River bottom. The first supply crib, built in 1897, was 32 ft. wide, 308 ft. long, and 5 ft. high, made of 2 by 6-in. and 2 by 8-in. planks, placed edgewise and flatwise, and separated by intervals of 2 in. A 24-in. pipe extended from the interior of the crib to the pump-well on the shore. The crib was sunk in a dredged excavation, about 300 ft. from the north shore of the river, and at a depth placing the top of the crib about 5 ft. below the natural bed of the river. The excavation was refilled and the crib covered to a depth of 1 ft., with 2-in. gravel, and then with from 4 to 4½ ft. of sand and fine gravel, such as had passed through a 1½-in. mesh screen. The depth of the water over the crib was ordinarily from 8 to 10 ft.

* New York City.

Mr. Fuertes.

It was shown by analysis of the water that the supply was drawn partly from the river by filtration through the gravel over the cribs, and partly from the sub-stratum of ground-water in the 30-ft. bed of gravel and sand in the river bottom.

In 1902, two additional cribs, each 48 ft. wide, 408 ft. long, and 5 ft. deep, were put in service. They were constructed in the same general manner as the first, but excluded from the gravel covering stones larger than 1 in. in diameter. Three cribs were sunk side by side and 10 ft. apart, and a line of 42-in. pipe, decreasing to 24-in. in diameter, was laid in the 10-ft. space between the cribs, with four short pipe connections therefrom to each crib about equally spaced throughout their length. The main 42-in. pipe was extended under the river bottom to the pump-well on shore.

The water from the cribs discharged under its own head into the pump-well, and was pumped thence to a reservoir, from which the street mains distributed it to the consumers.

After periods of operation of varying lengths, the surfaces of the gravel over the sunken cribs would become more or less choked with silt, dirt, and other matters suspended in the river water, and gradually fail to yield a sufficient supply. To relieve this shortage, the company had recourse to cleaning or washing the filter areas with water. The filtering area immediately over the cribs—with all three cribs in use—was about 1.13 acres; undoubtedly, however, water entered the cribs from the bottom and from areas outside of the boundary lines of the cribs. It is not possible, therefore, to state the rate of filtration per unit of area per day, except that it was less than about 7 000 000 gal. per acre per day by the quantity derived from sources other than the filtering area over the cribs.

The plan followed in cleaning these filter areas was to drag back and forth across the area a rake having a 2-in. pipe header, 3 ft. long with seven teeth, 15 in. long, each perforated with two $\frac{3}{16}$-in. holes on the front and one in the end, water being forced down through this rake at a pressure of 125 lb. per sq. in. by a pump on a barge. The rake was dragged across this area, the wash-water rising up through the sand and bringing the mud with it, the principle resembling that by which the Blaisdell filter washer is operated. The river current was depended on to carry the washings down stream and away from the washed areas. The rake was dragged back and forth across each area three times, by hand windlasses on barges anchored on each side of the areas being washed, before a new area was attacked.

Raking, or scouring, was practically continuous from May to November, 1905, and from May to December, 1906, except as interfered with by uncontrollable conditions, such as river floods. In 1906, the surface was examined several times by a diver, who reported

Mr. Fuertes.

considerable disturbances of the sand surface, and, under his guidance, depressions were filled up with gravel and sand deposited from a barge through a tube. Frequently, the diver rode on the rake, as it was dragged back and forth, to press the teeth down into the sand. It was stated that the teeth usually penetrated the top of the gravel bed to a depth of from 8 to 12 in. While the process of raking or scouring was going on, the cribs were kept in constant use. The disturbance of the surface and the destruction of the silt formation thereon permitted a largely increased volume of water to pass freely through to the cribs, through the washed areas, and during and immediately after these periods of washing, the water was easily shown to be very little different, in character, from the raw river water.

Much evidence was introduced at the trial as to the quality of the water, both as to its chemical and biological features, and it was shown that there were times when, for a number of consecutive days, the quality of the water would be excellent; all of a sudden, however, some change in conditions of river flow would cause the silt to be washed from the river-bed over the cribs, or parts of their areas, leaving places where the river water could penetrate to the interior of the cribs in a practically unchanged and polluted condition.

In 1905 and 1906, typhoid fever in Wilkinsburg became epidemic, and just prior to the bringing of the suit it had the highest typhoid fever case and death rate of any town in the United States. Very heavy rates also prevailed in the 37th Ward of Pittsburgh, and in Swissvale Borough, also supplied with water by the same company. As a result of this alarming condition, protests were lodged, and, finally, recourse was had to the Courts to compel the Water Company to safeguard adequately the quality of the water. The case, recorded as E. Z. Peffer *et al. vs.* Pennsylvania Water Company, was No. 396, tried in the August term, 1906, of the Court of Common Pleas, No. 3, of Allegheny County, Pennsylvania, Miller, J., specially presiding. The conclusions of law, in this case, as drawn by Judge Miller, were:

First.—The fact having been found that the water complained of, as furnished by the defendant, is not reasonably pure and wholesome, it follows that the plaintiff's bill must be sustained.

Second.—An interlocutory decree will be entered, directing it to secure and provide a sufficient supply of pure and wholesome water; further directing that it shall, within three months from the date of decree, file a statement of the steps it has taken, and purposes to take, in compliance with the requirements to furnish reasonably pure and wholesome water, upon the submission of which the plaintiff may file a reply or answer, as he may deem advisable. It will be further decreed that this case be retained for such further proceedings

Mr. Fuertes.

as may be necessary to insure its performance, and to enable the Court to exercise the jurisdiction conferred by this Act of Assembly under which this action is brought, with liberty on the part of either of the parties to apply to Court for further orders and decrees as may be necessary and just.

Third.—The defendant to pay the costs.

The meagerness of the data regarding the details of design, construction, and operation of the Parkersburg plant, in Mr. Hall's paper, makes extended discussion of it impossible. Those elements of design which would give control over the process of filtration are scarcely mentioned. Enough is stated, however, as to the diameters of the main pipes leading from the strainer system, and as to the sizes of the laterals and their perforations to indicate:

1.—That hydraulic conditions must exist which would be avoided in a properly designed filter plant.

2.—That there can be almost no control over the effectiveness of back-flushing, or washing of the filter areas.

3.—That the loss of head must vary between quite wide limits at various parts of these areas during filtration, and after partial clogging shall have taken place, and that, therefore, parts of the areas must be passing the water at much higher rates than others, and, consequently, must be doing less effective work than planned.

4.—It is also evident that the back-flushing is likely to blow up and overwash parts of the areas, and leave other parts badly clogged.

5.—That floods in the river may scour, and probably have frequently scoured, holes in the filters—possibly almost down to the strainers.

6.—That the whole filter area is inaccessible, and utterly beyond inspection and repair during floods, the times when the water is worst and the need of protection greatest.

The Parkersburg plant may be expected to give fair water when the river is in its best condition, and, at such times, it is almost good enough to use without filtration. When the river water is turbid and dangerously polluted, the water delivered by the plant may or may not be safe. Whether or not it is safe will be beyond the knowledge of the men operating the works; and, if it is unsafe, it is entirely beyond their power to make it so by any agency or device inherent to or part of the plant itself or of its design.

Judging by the discoveries of Mr. Leland, when making the inspections in September, 1916, referred to by Mr. Hall, the Parkersburg plant is experiencing difficulties similar to those which led

ultimately to the virtual condemnation of the Wilkinsburg works and to the erection of a properly built mechanical filter plant in its stead. Mr. Fuertes.

The cost of construction and operation of the works, as built at Parkersburg, are given by Mr. Hall as $284 171.22 and $11 892.46, respectively. The annual cost was based on the pumpage of an average of 3 000 000 gal. daily. In the Fuertes-Fuller report, the costs were given as $165 945 and $24 000, respectively, the latter figure being the estimated annual cost of operation for a daily yield of 4 000 000 gal. Reduced to the basis of 3 000 000 gal. daily, for comparison with the figures given by Mr. Hall for the Parkersburg plant, and adding to the cost of construction certain items included by Mr. Hall, and with interest at 7% in each case, the annual operating and maintenance costs of the two plants would be practically equal. The Smith system, therefore, has required at Parkersburg a greater investment, saves nothing in annual expense, and gives to the city far less security against water-carried diseases than would have resulted from the establishment of a properly built and operated mechanical filter plant, such as recommended and described in the Fuertes-Fuller report.

Mr. Hall gives, among the reasons advanced by Mr. Gray for the adoption of the Smith system for Parkersburg, that,

"If properly built and operated, this system will furnish water of a better quality than a mechanical filter plant, as regards steam-raising purposes, on account of the slight increase in permanent hardness which is caused by the use of a coagulant."

Although it is true that the use of aluminum sulphate as a coagulant will result in the conversion of a portion of the alkalinity into the sulphate or incrustant form of hardness, an examination of the analyses in Appendix I shows that throughout January, 1914, the total hardness of the water from the Smith system was about 87 parts per million, as against about 74 parts per million for the river water, this increase being due to the increased alkalinity of the sub-river ground-water. The increased quantity of soft scale due to the extra 13 parts per million of hardness of this ground-water is probably fully as disadvantageous from a steam-raising point of view as would be the conversion of about 5 or 6 parts per million of the low alkalinity of the river water into a proportional quantity of incrustants by the application of aluminum sulphate used in connection with mechanical filters. For summer conditions, when both the river water and the water secured by the Smith system would be much harder than reported in the January analyses, the advantages would probably lie strongly with the mechanically filtered water.

And, further, with the mechanical filters, the operatives would have access to and control over the filters and their efficiency at all

Mr. Fuertes.

times. With the Smith system, the whole delicate process of filtration is beyond reach, often buried under floods and subject to disturbance by wash and scour, or to irregular deposition of mud on the filter area, with consequent imperfect purification, due to varying and excessive rates of filtration on parts of the area smaller than the total required.

Taking everything into account, the speaker is not convinced, by the data brought forward, that the proper decision was made at Parkersburg when the Smith system was adopted in preference to a properly designed and constructed mechanical filter plant.

It is much to be regretted that so little information has been furnished as to the operation of and results obtained by the Parkersburg water-works plant. Fancied security has led to neglect of vigilance, as represented by systematic, continuous, analytical studies of the river and secured waters, and more frequent examinations of this nature, as recommended by Mr. Hall, should certainly be made by the authorities.

The ground-water studies, made at Parkersburg, and referred to by Mr. Hall, show a number of interesting facts. Figs. 3 to 12 were selected from among 32 such diagrams in the Fuertes-Fuller report, and seem to have been well chosen to exhibit the interesting phenomena of filling and emptying the subterranean storage spaces in the voids in the gravel underlying the flat lands along the river north of Parkersburg.

It will be noticed that the water finds its way into the ground, from the river, with comparative difficulty, as judged by the steep slope of the ground-water in the neighborhood of the river banks, but that it makes its escape back into the river, when the latter falls, with comparative freedom. This is as would be expected, the surface of the river bottom and banks having become clogged with mud (strained out of the river water as it filtered out through the banks and bottom) on a rising river, but being cleansed, or washed free of mud to a greater or lesser extent, on a falling river, by the passage of the ground-water back again into the river.

The contours on Figs. 16, 17, and 18 show the gradual change in direction of the flow of the ground-water away from and toward the river above Parkersburg. Fig. 12, which was reproduced from among the diagrams in the Fuertes-Fuller report, occupies a position between Figs. 17 and 18. An examination of these diagrams shows the following interesting conditions.

On January 13th (Fig. 16) the river, after having reached its lowest point from a previous rise, was just beginning another rise which, by the 15th, had reached 9 ft. Observing the ground-water contours on this diagram, it will be seen that the general trend of the ground-water was down stream and toward the Ohio River,

Mr. Fuertes.

the 571-ft. contour being the farthest down stream and the 574-ft. one the farthest up stream, all these contours lying in approximately parallel lines, and indicating a motion diagonally down stream toward the river.

On January 17th, the river began another rise, and, within the next few days, reached an elevation of 597.5 ft. On January 19th (Fig. 17) it stood at Elevation 592. It will be observed that the contours of the surface of the ground-water had changed entirely, swinging around parallel to the shore with the highest contours (Elevation 579) along the river bank, and the lowest still at Elevation 572, on a line parallel with and about 2 000 ft. distant from the river bank. By the 24th, the river surface had fallen to 692.5 and the ground-water near the river bank had risen to 584, or 14 ft. higher than on January 13th, whereas, along a line practically parallel with, and some 2 500 ft. east of, the river bank, the ground-water level had risen only about 1 ft.

On February 5th (Fig. 18) the river still continued to fall, the ground-water which had been piled up to Elevation 584 on January 24th had fallen at the river bank to an elevation of only 573, gradually rising to an elevation of 575, about 2 000 ft. back from the river and dropping to 574 a few hundred feet farther east. In this case the water was slowly flowing in both directions from a line parallel to and about 2 000 ft. back from the river bank.

It is very fortunate that this flood occurred during the time that the tests were being carried on at Parkersburg, as the occasions on which such phenomena can be observed are relatively rare.

Mr. Fuller has made the suggestion that in a short time the results of studies for the more complete identification of certain forms of bacteria will be made public. The present laboratory methods for the quick determination of the probable presence of *B. coli* in water, are, as Mr. Fuller has said, not only far from satisfactory, but actually misleading under some conditions. An accurate and extensive knowledge of the history of the water is always essential in determining the likelihood of the presence of these organisms, if shown to be probably present by laboratory tests. The speaker calls to mind an interesting experience of this sort in connection with the examination of the water supply of the Insane Asylum at Willard, N. Y., in December, 1901, and January, 1902.

Diphtheria had been epidemic at the Willard Asylum since 1897, and all efforts to eradicate it from the institution had proven unavailing. The cases were confined mostly to the nurses, physicians, and attendants, very few cases being noted among the inmates. The superintendent of the asylum and his wife were both in quarantine with diphtheria while this investigation was going on. In connection with the various studies made to determine the cause of the prevalence of

Mr. Fuertes.

the disease, a thorough examination was made of the water supply and sewerage of the institution. In order to eliminate possible sources of error, a great many samples of water, from widely separated locations, were collected and examined.

The water supply for the institution was taken from Seneca Lake at a point some 400 or 500 ft. from shore, where the water was about 30 ft. deep, and at a point about 1 800 ft. from where the main sewer of the institution discharged into the lake.

An apparatus was devised for securing samples of lake water at various depths, and these, after collection, were put in sterilized, glass stoppered bottles, and examined promptly.

Samples were taken at the surface of the lake and at various depths at numerous points, some of these being in the immediate vicinity of the sewer, some at the water-works intake, others on the opposite side of the lake, about 1½ miles from the intake, others at the ends of the lake, more than 20 miles distant. The samples were collected at various depths, from the surface to 300 ft. below the surface.

These analyses disclosed the interesting fact that the chlorine content of the lake water varied from 36 to 37 parts per million, which was about one-third of the quantity that might be expected in ordinary town sewage. Organisms giving the reactions expected of *B. coli* were found in the samples collected in the neighborhood of the sewer, also, in samples collected 50 ft. below the surface on the other side of the lake and about 600 ft. from shore, also, in some collected 50 ft. below the surface, some 600 ft. off shore about 2 miles away, and in a number of other places. Previous analyses made in 1899 had disclosed the suspected presence of *B. coli communis* in samples 1 300 ft. out from shore, on the line of the hospital's sewer, at a depth of 20 ft.; ½ mile from shore at a depth of 150 ft.; ½ mile from shore on a line with the water-works intake at a depth of 400 ft.; 500 ft. deep off shore about 5 miles south of the Asylum, and in the center of the lake at a depth of 400 ft.

In the analyses made in 1901-02, it was pretty well established that the organisms giving the reactions for the differentiation of the *B. coli communis* were probably washed into the lake from the cultivated fields along the sides, and bore a close relation to the rust on grain.

The high chlorine in the lake water was caused by the presence of underground salt beds in that vicinity; the normal chlorine for that region would not be more than 7 parts per million.

Without knowing all the conditions, the analyses of Seneca Lake water might easily have been mistaken for a highly sewage-polluted

Mr. Fuertes.

water; a conclusion which the most ordinary common sense would refuse to accept.

More positive methods for identification of sewage bacteria in waters have long been needed, and water-works engineers will welcome the greater certainty promised by Mr. Fuller's predictions.

Messrs. Knowles and Stevenson.

MORRIS KNOWLES,* M. AM. SOC. C. E., and J. D. STEVENSON,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is of especial interest to the writers, because of the part they took, in 1908-09, as Consulting and Resident Engineers, respectively, of the Water-Works Commission, in the early studies of the water supply at Parkersburg and the proposed new systems. They believe that a statement of some of the considerations which led to the recommendation to develop a well supply, instead of the system described by the author, will be of interest. The author is to be commended for collating and bringing before the Profession the various studies and reports which have been made in reference to this interesting situation.

No discussion of this subject would be complete without mention of the lively interest taken in these early investigations by the late United States Senator J. N. Camden, and continued, at his death, by his estate. The generous attitude of this public-spirited citizen can be best stated by quoting from an open letter from him to the city officials, as follows:

"I, therefore, respectfully propose, in order to test the question of natural filtration, that I will, at my own cost and expense, sink and test wells, both on the river front and on the foot of Neal's Island, for which I already have the permission of the owner, to ascertain the quality and quantity of water that can be obtained by natural filtration, and to commence as soon as the engineers selected by the city authorities and water-works commission are ready to direct and superintend the tests to be made. This will cost the city nothing and will no doubt be of value in arriving at conclusions. I will also add that, should the city desire to locate its plant or pumping station or wells upon any ground owned by me, I will donate to the City all the ground it may need for water-works purposes."

In pursuance of the engagement of the writers as engineers, a report was made on August 24th, 1908, covering an investigation of ten possible developments and including a recommendation that either a mechanical filter plant or a system of wells be adopted as a source of supply. A definite choice between these two projects was not recommended at that time for two reasons: First, because the original sum of money appropriated to the Commission did not permit of drilling and testing wells; and, second, because after the money donated by Senator Camden for this purpose was made available, it was concluded "that the time was not propitious for either drilling

* Pittsburgh, Pa.

or testing wells, as both the river and the ground-water level were too high to justify any conclusion from a test as to safe yield."

Messrs. Knowles and Stevenson.

The investigation of the wells was only postponed, however, being carried out in the succeeding warm, dry season, at a time when both surface and ground-water levels were low. The conditions at the time of the tests were most favorable to a safe conclusion, as the river was lower than it had been for many seasons. The results of these tests warranted the recommendation of a water supply to be drawn from wells on the Camden Farm, which was reported on January 25th, 1909.

The topography, geology, and history of the Ohio Valley give evidence that, at one time, either the Little Kanawha River or Worthington Creek, or both, flowed through a gap in the hills and into the Ohio River at a point near the present settlement of Beechwood. In later years, either the Little Kanawha River straightened its course and shifted to its present location, while Worthington Creek occupied in reverse flow what had been the Little Kanawha River bed; or else, Worthington Creek cut a new course into the Little Kanawha River and thence into the Ohio. In any case, the gap in the hills became filled with sand and gravel, forming what are now known locally as the "Sand Plains", separated from Parkersburg by the rocky promontory known as Boremans Hill.

Evidence is conclusive that in times past the Ohio skirted the West Virginia shore and, at one time, occupied the area now forming the east shore terraces, on which are the Camden Farm and the settlements of Beechwood, Vienna, and Brisco. It is also evident by the slope of the rock that, in its former location, the Ohio River was at a lower elevation than at present, the intervening space between the present and the former beds having been filled with a water-bearing sand and gravel formation. The trough made by the intersection of the rock beds sloping from the two shores is under the east shore terraces, and, at the Camden Farm and for many miles up stream, probably has the same general course as Pond Run.

The flow of underground water normally follows the general inclination of the rock, and is outward from the surrounding hills. When the flows from two hills meet, the resultant flow is upward, and if it is abundant and the head is sufficient, an Artesian flow will result. Such is the origin of much of the flow in Pond Run. An inspection of the bottom and sides of the Run and feeders will disclose many springs, and these have been found from above Neal's Island to a point below the Camden Farm.

It would not be expected that there would be a large flow parallel to the river in the sand and gravels directly over the rock, but rather that something like an underground reservoir would be formed, over-

Messrs. Knowles and Stevenson.

flowing into the river and to the surface of the terrace. However, in this particular case, the gravel beds are topped by impervious clay and loam. As a result, the head due to the higher level of the ground-water on the "Sand Plains" causes flow in the direction of the inclining floor of the gravel beds, which is not only toward the river, but also down the valley. This was the basis for the proposed development by two lines of wells, one parallel to, and another at right angles to, the river, thus intercepting whatever water flowed toward or parallel with the river.

It will be noted that the top of the gravel beds at the river's edge is very little higher than the low-water level in the river. The observations made by the writers indicate that the underground reservoir is not fed to any great extent by infiltration from the river, but probably receives most of its water from rainfall on the terraces, on the "Sand Plains", and from the 26 sq. miles of drainage area tributary to Worthington Creek, and probably some from entrance at the rock riffles in the Ohio some distance up stream.

In Figs. 3 to 10, inclusive, it will be noted that the surface of the ground-water as shown is always above the line of demarcation between the water-bearing sand and gravel and the impervious loam and clay; and that in no instance did the pumping lower the surface of the ground-water into the sand and gravel. It may be concluded, therefore, that, even at high stages of the river, no large quantity of river water would be forced into the sand and gravel; for these strata would always be filled, and, as the impervious clay and loam above would not absorb water in quantities rapidly, the rise in the river would only increase the head on the water in the sand and gravel, raising the level of the water in the observation wells correspondingly.

Referring to Fig. 11, the following explanation appears in the writers' report:

"When pumping was checked in amount or stopped entirely, the water quickly rose in the well being pumped, indicating a lack of strainer openings for the free access of the water."

In the absence of long-continued tests, the quantity of water which may be procured from any formation is largely a matter of speculation. The planning of a water supply from wells in any undeveloped territory, therefore, should provide, where possible, for permitting easy future adaptation to other sources of supply, in case this should become necessary. The conditions on the Camden Farm were particularly advantageous for such a water-works development; and, although, as a result of the tests and the comparison of conditions with those in somewhat similar deposits elsewhere, the conclusion reached by the writers, that wells, properly located, drilled, and developed, would yield continuously, for a sufficient period, all the water

Messrs. Knowles and Stevenson.

to be reasonably demanded by the City of Parkersburg; at the same time, the various units could be designed so as to be readily adapted, with a minimum monetary loss, to use in connection with a filter plant, to provide against the remote possibility of failure of the wells.

The estimated cost of the construction recommended by the writers was $220 865. Of this sum, 54% was for distributing reservoir, reinforcing mains, etc., and would be equally useful in connection with the water-works then existing, or with any other that might be designed; 33% was for pumping stations and equipment—structures equally useful, either with a filtration plant, or with a well supply; and only 13% was allotted to equipment useful for a well supply alone. Thus, it is evident that, even if the wells were to be abandoned at some future time, the loss on the investment would be trivial, and fully met in such times by the lesser cost of operating the well system.

Among the various developments studied in connection with the writers' investigation at Parkersburg was that known as the Smith infiltration system. The four principal reasons advanced at that time by the promoters for its adoption were: Economy in installation and operation; purified river water and not hard ground-water; ease of repairs and replacements; and reliability of supply. Instead of confirming any one of these points, the investigation of the writers decidedly discredited all of them and, further, led to the conclusions: that the infiltration system, being submerged in the bed of the river, is subjected to the shifting of the river bottom, and to uncontrolled variation in the thickness of the covering over the strainers; that such variation, whether increase or decrease, would be detrimental to the process, and that the infiltration system, being below the low-water level, cannot be subjected to the same accurate control and careful observations and studies of operation as are possible with a modern filter; furthermore, that the only method of cleaning the beds is by back-flushing, and that such a procedure, without controlling devices for guaranteeing an even distribution of the wash-water, may do decidedly more harm than good; and, finally, that the danger of the introduction of polluted river water into the system was ever present. A special report, dated January 15th, 1909, therefore, recommended that it was unwise to introduce such a system. It is now evident that several of the difficulties foreseen have already occurred; the author's account of the replacements during the summer of 1916 point to this fact.

The investigations of the Pittsburgh Filtration Commission in 1907-09, with which one of the writers was connected, showed that no system of filtration, without a sufficient period of subsidence, will effectively treat the Allegheny River water; and that, if the rate of filtration is increased to more than the normal moderate rate of slow sand filtration, a coagulant must be used. The investigations at Cin-

Messrs. Knowles and Stevenson.

cinnati fixed an average of 125 parts per million as a conservative estimate of the suspended matter in the unsubsided Ohio River water, which could be treated regularly and fairly satisfactorily by slow sand filters. On this basis, a slow sand filter without a period of subsidence would be a failure 65% of the time, if treating this river water.

For all these reasons and because of the many points of inferiority of the Smith infiltration system, when compared with the modern slow sand filter, designed, constructed, and operated in accordance with accepted engineering practice, a negative recommendation on the Smith system was made.

There is, however, nothing new or novel in the Smith infiltration system. Although it was claimed to be an improvement on and substitute for the established method of slow sand filtration, in reality it resembles more nearly, both in principle and in practice, the "filter cribs" which have been used for the supply of water to communities along the Allegheny and Upper Ohio Rivers, and, no doubt, on many other streams, for more than 20 years. In most cases, the construction of the latter consists of a large wooden crib, open at the sides and bottom, placed in an excavation in the river bed, and covered on top with from 5 to 7 ft. of selected sand and gravel.

At the time of the investigations, by the Pittsburgh Filtration Commission, of possible sources of water supply for that city, considerable study was given to the results obtained through filter cribs. Analyses of the river water and of effluents from the cribs indicated that, in general, the effluents from the cribs were clear and free from suspended matter, except at extreme high stages of the river, and that the number of bacteria in the effluents were usually less, but the hardness materially greater, than that of the water from the river itself. The Pittsburgh investigations showed clearly that, early in the life of the cribs, much or all of the water is drawn from the sand and gravel beds lying under and around them; but that, with age, the sand and gravel beds become clogged, and larger and larger quantities of water are drawn down from the river through the top covering. In many cases this downward flow is increased by raking the sand covering, and although the top covering may be broken up in this way or even replaced, it is impossible to clean efficiently the material under and around the crib. With the increased infiltration direct from the river through the top, there is a corresponding deterioration in quality. These statements are fully confirmed by the experience of the numerous water plants with crib supplies which have been obliged to supplement these with filter plants within the past few years.

The author has expressed the opinion that a large percentage of the water drawn is taken from the sand beds, possibly a larger part than that from the open river. This opinion is quite in accord with the experience of the writers, and it would appear not unlikely that

Messrs. Knowles and Stevenson.

during the early life, while the strainers are new, and before the strata at the bottom and sides become clogged, 70% or more of the total water may be drawn from this lower bed. The so-called filtered water, therefore, is in large part a ground-water, similar in chemical characteristics to that which would be had from wells; and in so far as satisfactory results with respect to quality are secured, they are without doubt due more to the quality of the ground-water than to the efficient filtration of the river water. Nor would it be safe either to predict how long the situation might continue, or to expect other than unsatisfactory results with the increase of the proportion of river water. Back-flushing, if forceful enough to be successful, invariably results in disturbing the sand layers to a dangerous degree and frequently forms craters or troughs of washed material, leaving the rest of the bed undisturbed and uncleansed.

It is worthy of note also that, at Parkersburg, the decision between a well supply and a supply by mechanical filtration was a very close one. Either system was considered certain to provide a safe, abundant water supply for the community, and both systems had the endorsement of the best engineering practice and were sanctioned by the most exacting Boards of Health in adjoining States. The system adopted had none of these assurances, and was closely akin to a practice which has been condemned, and is rapidly being abandoned in neighboring States, for water supply for domestic purposes. It would seem that the time is fast approaching when most of the expenditure of $80 700 will be required to be renewed or replaced by some other system.

If the story of the development of the Parkersburg Water-Works might be permitted to point a moral, it would seem to be that of the advantage to be gained by every community in having a sovereign State organization, the duties of which should include investigations and experimental studies on all problems concerning water supply and sewage disposal. In this manner a large fund of valuable information might be collected, placing the supervising body in a position to advise local authorities in these matters in an impartial way and with freedom from the pressure of local controversial opinion. Fortunately, this has since been recognized in West Virginia, by the re-organization of the State Board of Health, and the addition to its staff of a competent sanitary engineer. Had the State had such an organization at the time of the adoption of the present water supply system, and had the City been obliged to have that Health Department approve the installation, the community might have been spared the expense of having many different engineers make separate investigations, only to disregard at the end the recommendations of most of them, and to put in a system which was largely experimental and in the adoption of which the theory and practice of water-works engineering was probably not the sole consideration.

Mr. Tolman.

EDWARD MAYO TOLMAN,* JUN. AM. SOC. C. E.† (by letter).—This comprehensive and valuable paper, together with the discussion on the so-called Smith system of filtration which it has evoked, has been of special interest to the writer, as that system has been made the subject of several bitter political controversies, into which one side or the other has endeavored to drag him, ever since his appointment as Engineer for the State Health Department, with demands that he either praise the system to the skies, or condemn it as utterly worthless. It was so evident that both sides, for the most part, had so far lost all sight of the engineering principles involved, that a careful report on the system would in no way change the opinion of those interested, but might serve as political capital, that the writer, heretofore, has refrained from an expression of opinion. Nevertheless, the Division of Sanitary Engineering of the State Department of Health of West Virginia has gathered considerable data on the system, some of which may prove of interest.

Beginning in January, 1917, the Department, once a week, has made complete chemical examinations of samples of the Ohio River from directly over the surface of the filters and from a tap in the City Hall. The results of five pairs of samples are given in Table 5.

These results would be of greater value if analyses of water from wells along the river bank were available for comparison. The series of samples were collected primarily for the purpose of showing the percentage of ground-water in the city supply, but the well samples showed such high contamination that the results are of no value in the present discussion. The State Chemist, Mr. Alton A. Cook, in commenting on these results, states:

"That practically no ground-water enters the supply is shown by the figures for ammonia, nitrates, hardness, and alkalinity, since typical pure ground-water would make a greater decrease in the figures for free ammonia than is shown here, and the analytical figures for nitrates, hardness, and alkalinity would tend to be considerably increased under these conditions."

This opinion is interesting, as it is generally thought that from 20 to 40% of the water collected in the Smith system at Parkersburg is ground-water. In the writer's opinion, the samples represent very special conditions which can occur only when there has been a rapid rise in the river following a considerable period of low stage, during which the ground-water has had a chance to run out. At Gallipolis, Ohio, and Owensboro, Ky., where somewhat similar systems have been adopted, it is claimed that they are filtering river water, not ground-water, and it may be that such is the case at Parkersburg. However, at Newell, W. Va., where the water supply is obtained from submerged

cribs, 4 ft. below the bed of the river, the contrary is certainly true, as shown by the three analyses in Table 6.

It is evident that, at this town, from 60 to 80% of the water is derived from the underground-water stratum, and is not filtered river water. Similar conditions obtain at Chester, Wellsburg, and other West Virginia towns along the Ohio River, which derive their water supplies from cribs or wells in the river bed. The underground waters along the Ohio in this State are very hard, and it is probable that sufficient underground water is entering the Parkersburg system to raise the hardness of that supply, during a large portion of the year, above that of a filtered river water, such as would be obtained by rapid sand filtration.

Next, considering the character of the water from the standpoint of turbidity and color: No analyses of the tap water made at the State Laboratory have ever shown either color or turbidity. The highest turbidity recorded by Dr. L. O. Rose, of Parkersburg, who made daily tests throughout 1913 and frequent analyses since then, was 15. This followed a flood in the Miskindum River which empties into the Ohio a few miles above Parkersburg. At the time of the flood, Dr. Rose informs the writer, the results of ten very careful determinations of the turbidity of the Ohio at the filtration plant showed 25 000 parts per million, almost, if not quite, "straight mud." In the fall of 1916, the writer had one of his assistant engineers, Mr. Ellis S. Tisdale, visit some 200 residences and places of business in Parkersburg and inquire whether any turbidity had ever been noticed in the city water and whether the water had always been satisfactory from all other stand-

points. Not a single person interviewed had anything but praise for the supply. Mr. Tolman.

That the filtered water has not been highly turbid at times is remarkable, when some of the details of construction of the plant and of operation are considered. With the present design there is no method of telling what proportion of the water is passing through each filter unit. This is particularly dangerous, when it is considered that the pumps suck the water from the collecting manifolds. Thus, if the cover over any one filter should happen to be very thin, this unit would be operated at too great a rate. The water should flow by gravity from the collecting system to the pump-well, and each filter unit should be provided with a rate controller or a recording Venturi. Such devices would furnish data for the intelligent control of the filters. As it is, back-flushing is now conducted with no rhyme or rhythm, as can be seen clearly from an examination of Table 7, which shows a range of from only 1 300 000 gal. pumped per flushing to more than 92 000 000 gal.

* Meter stopped.
† Filters cleaned.

The frequency with which the filters are flushed at present depends in no way on the quantity of water pumped or the character of the water. It is the writer's opinion that, in the absence of any controlling devices on the units, daily tests of the turbidity of the river should be made, which, combined with the stage of the river, whether rising or falling, and the quantity of water pumped, would probably serve as a basis for more intelligent filter operation. As it costs approximately $5.80 per million gallons to pump the water, and as between 40 000 and 50 000 gal. are used in a single flush, it will be seen that back-flushing has cost as much as $100 per month, a figure which could be reduced materially if more thought were given to the problem.

Mr. Tolman.

As to the purity of the water obtained by the so-called Smith system, at Parkersburg: The analyses made by Dr. Rose, up to the spring of 1916, showed a bacterial efficiency ranging from 95 to 100%, with an average of about 98.8 per cent. In the spring of 1916, the analyses made each month by the State Hygienic Laboratory began to show high bacterial counts and the presence of the colon organism in the filtered water. Dr. Rose then started making check analyses, and obtained similar, though less pronounced, results. To correct this condition, the city, in June, 1916, erected, in the pump-house, a Wallace and Tiernan chlorinating plant. The public has never been advised of this fact for fear that all manner of tastes and odors would be detected immediately. The results of the bacteriological analyses have been more satisfactory since chlorination was begun, but the count is still higher than it should be, and the colon organism is frequently encountered in 10-cu. cm. samples. It is possible that the *coli* found are entering at the reservoir. The water in the reservoir, owing to the location of the inlet and outlet pipes, has very little circulation, and probably some of it has stood there for many months. Dr. Rose informs the writer that samples taken at a depth have always shown a marked colon content.

In commenting on the results of the chemical analyses (Table 5), Mr. Cook states:

"In general, the purification is not all that can be desired, as shown by the figures for ammonia (free), nitrates, and oxygen consumed in one or more of the last three samples. The city drinking water, on the whole, is of fair quality, but there is room for improvement, before it can be considered a first-class drinking water."

It may be said, however, that Parkersburg has a satisfactory and safe water supply which is being delivered to the consumer at very low cost.

The writer has frequently heard the so-called Smith system of filtration condemned, on the ground that it cannot produce a safe or satisfactory water. This, he feels, is a mistake. At Owensboro, Ky., Gallipolis, Ohio, Chester and Newell, W. Va., and at other places using systems in many ways similar to that at Parkersburg, the water is satisfactory, both from chemical and bacteriological standpoints. At Chester and Newell, the colon organism has never been encountered, to the writer's knowledge, and yet no disinfectant is used.

It is the writer's opinion that the Smith system of filtration can furnish a satisfactory water at a low operating cost, provided nothing happens to injure the under-drains in the river, the problems of proper back-flushing being largely those of design and operation. It would appear then that, other things being equal, the choice of the Smith system over a rapid sand filter hinges on a gambling chance, the engineer betting that nothing will happen to the collecting drains against

the high cost of chemicals. If he wins, the profit to the city is large, but, if he loses, the city may pay in life, as well as in money. Mr. Tolman.

An interesting example of what may happen is afforded by experience at Wellsburg, W. Va., in 1916. The water supply of this town is derived from wells in the Ohio River, about 100 ft. from the shore. These wells are constructed of 60-in. cast-iron pipe set vertically in the river bed, with their upper ends 3 ft. below the surface of the sand. The bottoms of the pipes were left open, but the tops were sealed with iron caps leaded into the bells of the pipe.

The main suction line from the wells to the pump was provided with four branches, each branch extending through the cap of one of the wells. This system had been in use for a number of years, and had furnished a satisfactory drinking water. In the spring of 1916, however, one of the wells began to settle, which caused a crack in the suction main, and raw water entered the system. A typhoid outbreak of several cases and one death followed shortly.

When the supply was first used, it was possible to go back and forth in rubber boots over the surface of the sand-bar in which the wells were placed, consequently, the cost of the original construction was comparatively small. Since then, however, the Federal Government has built a dam across the Ohio just below Wellsburg, increasing the depth of the water over the bar by several feet. Investigation has shown that the cost of repairs to the well system would be almost prohibitive, and the town contemplates abandoning the present supply entirely and looking for a new source.

That a similar accident might happen to the Parkersburg system is shown clearly by the finding last fall (1916) of the broken strainer pipe which nearly caused a blow-out in the sand bed.

However, it must be stated that considering the lack of skilled attention given to this plant since it was put in commission, it has shown remarkable results. The plant is virtually in charge of the man at the pump, who, although very able, does not have the intimate engineering knowledge necessary for the proper operation of a practically untried form of filtration. The Water Commissioners are not trained engineers, and their supervision extends primarily to the financial side of the water-works problem. Parkersburg has adopted a very short-sighted policy in not placing a trained man in charge of the operation of the plant, and the fruits of this policy are now being noticed. It is probable that, if the plant had been operated scientifically, instead of in the hit-or-miss fashion of the past, the results would have been more to the credit of the system.

WILLIAM M. HALL,* M. AM. SOC. C. E. (by letter).—The writer is gratified with the extent of the discussion, and wishes to express his appreciation to each of those who have contributed to it. Mr. Hall.

* Parkersburg, W. Va.

Mr. Hall. The preliminary investigations for a new water supply for Parkersburg were commenced by Senator Camden—at his own expense—as early as about 1903, and were continued from time to time until Mr. Knowles was engaged in 1908. During this period he conferred with the writer many times. As stated by Mr. Fuller, two factions of the citizens were developed, one led by Senator Camden favoring a well supply, and the other led by the mayor of the city at that time, favoring a mechanical filtration system. Senator Camden spent several thousand dollars of his personal funds in extending the information as to the available natural supply obtainable from wells, and, besides, devoted much of his time to gathering information, locally and in the Ohio Valley, relative to the subject. He also presented the city with a tract of 43 acres for water-works purposes, but this was lost by the failure to adopt the well system.

The mayor in office at that period was skillful enough to use the subject so as to obtain two elections therefrom, but, on the third, it resulted not only in his complete downfall, but also in changing the three-headed form of city government—consisting of a council, board of affairs, and mayor—to one of simply a mayor and four commissioners working as a single body.

Mr. Johnson and others who wish for more data on the investigations by Mr. Knowles and Messrs. Fuertes and Fuller, in reference to the natural available well supply on the Camden Farm, the capacity of the wells, the comparison of the several waters chemically, the bacteria, *B. coli,* and bacteria count, should obtain printed copies of these reports from the city clerk; they contain many valuable data, too extensive for this paper.

A copy of the test made under the direction of Edward Mayo Tolman, Jun. Am. Soc. C. E., Chief Engineer of the State Board of Health, for the fiscal year past, as prepared by him and given out for publication under date of August 13th, 1917, is given in Table 8.

In a further report, in reference to this supply, Mr. Tolman says:

"The Parkersburg water supply is undoubtedly safe for consumption. * * * A few samples have been pronounced unsafe, and a few more suspicious. Some of the unsafe samples are undoubtedly due to the length of time elapsing between their collection and analysis. To be truly representative of the water, an analysis should be made within a very few hours after the sample has been collected, and yet at least one set of samples was 5 days in reaching the laboratory—ample time for the bacteria present to develop in untold numbers.

"As for the poor samples that cannot be accounted for in this manner, you must realize that Parkersburg has practically, if not actually, the only filter plant in the State that is not using large amounts of chemicals to obtain a satisfactory water. The addition of these chemicals is a large factor in reducing the number of bacteria. If Parkersburg will slightly increase the amount of chlorine now used,

Mr. Hall.

S Safe. ‡ Tap undoubtedly safe.

Mr. Hall. the bacteria contents of her drinking water can be made as low as that in any supply in the State. I have instructed one of my assistants to tabulate the results of analyses, and I am enclosing these data herewith.

"You will note that pump house samples have but seldom shown *coli*, one of these times, 8/10/16, evidently being a fluke, as the *colon* was found, yet no bacteria were present; a second was found in a set of samples that was five days in transit, and the third and only other time in a set of samples in which both the tap and reservoir showed up remarkably well."

In consideration of such a showing as to quality and cost, and the further fact that Mr. Gray, who passed on the final design of the infiltration system in use, has a professional experience of such wide extent as to be equalled by very few of his professional brethren, it appears that Mr. Fuertes's strictures on page 824 might have been best withheld until the Parkersburg system is more thoroughly tried out.

The writer omitted descriptions of the filters and their operations for the reason that they could be given better by Mr. Gray or his assistant, Mr. Leland. As they have not done this, the writer will answer briefly some of the queries suggested in reference to the general design.

Referring to the plan of the filter system (Fig. 14): Each of the five units in the system is connected independently with the pumps and flushing tank by an 18-in. pipe, with valves for shutting off one or more units from the remainder of the system, for back-flushing or cleaning the filters. At first, 12-in. pipes were proposed, but 18-in. pipes were adopted, in order to reduce friction and vacuum, and to regulate the supply better when flushing.

The design first considered for the pump, well, and pipes provided that the strainer pipes should flow into the well by gravity, which required a well some 20 ft. deeper than built. The writer still questions the advisability of the change in the plan. The principal objection to the arrangement as constructed is the vacuum produced in the suction pipes and the resulting injury to the filter beds by the great increase in the draft on them.

In flushing through the 18-in. pipes, the flushing water can be delivered to the strainer pipes with any desired rapidity or pressure. It is true that the water issuing from the strainers will take the line of least resistance in rising to the surface, and it is almost surprising that so few blow-holes have been found. However, the writer realizes that they might become a serious source of contamination.

The best method of removing the sand and gravel covering the strainer pipes, the extent of such needed renewals, the necessity of

repairing the pipes, and other requirements of operation which will occur as the system grows older, are yet to be developed. However, it is now apparent that extensive work in sand renewal or cleaning will only be required at intervals of several years. When such examination is made, should it be found that the polluted sand and gravel extends all the way down to the strainer pipes and that a coffer-dam is required for such renewal, even in that case, the cost should hardly equal half the cost of first construction. Should it be found that it is necessary to renew only the top sand, and that the work can be done in the wet, without a coffer for unwatering, it will cost only a small fraction of the first cost. Since the filters were constructed, the Government has built a dam in the Ohio River below them, which at pool stage puts about 11 ft. of water on them. Mr. Hall.

The writer is of the opinion that the City should be advised at all times of the extent and depth of the pollution, both in order to maintain the water at a higher standard of quality and also to be able to renew the affected sand and gravel before the pollution approaches so close to the strainer pipes as to affect seriously the quality of the water or make a coffer for cleaning imperative. However, thus far, the system has been operated without any such knowledge or any attempt to obtain it. In fact, except for the back-flushing and the 3 or 4 days' work done by Mr. Leland in the fall of 1916, no work has been done on the filters since their construction, not even to the extent of taking soundings in order to discover blow-holes.

From Mr. Tolman's commendation of this system, as previously cited, it is not clear that the State Board of Health would take such action as suggested by Mr. Knowles. In fact, it appears that any city having similar favorable conditions for such a water supply would have no serious trouble in obtaining the State Board's approval for a similar plant.

It may also be well to remember that the State Board is a creature of the State and the people, and this is a day when the autocrat of state, religion, and science seems to be passing.

When this system was adopted, the writer thought the conditions for a well system were so favorable that it was unwise for the City to take the hazard involved in the experimental system adopted; but his associates were so much in favor of doing so, on Mr. Gray's recommendation, that the writer finally concurred with them. The fact that the system in use has its source in the same underground supply as the proposed wells would appear to be more of a commendation than otherwise. After further study, he thinks that Mr. Knowles will conclude that there is a great difference between it and the old failing crib system tried by so many Ohio Valley towns.

On page 825 Mr. Fuertes makes a comparison of the cost of the mechanical filter system proposed by himself and Mr. Fuller, with

Mr. Hall.

a statement of cost of the new construction as actually made. The details of their estimate, as taken from their report, is as follows:

Intake and intake well	$4 000
Filtration plant complete	50 800
Low-lift pumping equipment	3 000
Main pumping station, including all machinery except low-lift pumps	51 000
Dike and grading	10 000
Force main to reservoir	25 500
	$144 300
Add 15% for contingencies and supervision	21 645
	$165 945

A comparison of this estimate with the statement of the completed work on pages 780 and 781, including many things not in their estimate, is hardly relevant.

The following are the only items in their estimate which are of importance in making a comparison of the filters:

Intake	$4 000
Filtration plant	50 800
Low-lift pumps	3 000
Dike and grading	10 000
	$67 800
15 per cent	10 170
	$77 970

These are the figures the Commission used in comparing the cost of the mechanical filter with the one included in the Smith contract. The contract price was less than the foregoing estimate. With some additions, made after the first letting, the final cost was $80 700. This included all the work in the river, and the suction pipes up to the pump well.

As stated in detail by Mr. Burgess (page 813), Mr. Fuertes estimated the cost of operating the mechanical system proposed by himself and Mr. Fuller, with the pumping station, at $24 000 per year.

After looking over the accounts of the actual operation of the system in use for the past two years, in connection with the entire department accounts, the writer feels satisfied that the cost of operating the pumping station, including all the costs of putting the water in the City Reservoir and service pipes, has been less than $12 000 per year. Therefore, in the period during which it has been in

operation, as compared with a mechanical filter, as estimated by Messrs. Fuller and Fuertes, it has effected a saving of not less than $65 000. Mr. Hall.

There are only five men in the service of the City operating the entire pump station, day and night. As given in detail on page 781, the cost of managing and operating the filters has been insignificant, as compared with the requirements of a mechanical system, and the effluent is unquestionably much more pleasing to the consumers than some of the water from mechanical systems.

Relative to this matter, the following figures and data obtained from the City Auditor's report of accounts for the fiscal year ending June 30th, 1917, are interesting and pertinent:

"No payment has ever been made for either the old water-works system or the new, for either construction, maintenance, or operation, except that obtained from bonds and for water rentals. The average rate collected for metered water during the fiscal year ending June 30th, 1917, was 7.33 cents per 100 cu. ft., or per 748 gal. During the year the quantity of water which passed through the pump station, as measured by a Venturi meter, was 170 000 000 cu. ft., or an average of 3 484 000 gal. per day.

"54 483 061 cu. ft. passed through the consumers' meters, for which the city received about $40 000.

"From consumers paying monthly rental it received about $20 000."

Therefore, it appears that a little less than half the water pumped produces all the revenue, and the remainder was used for sprinkling, fires, sewer flushings, leakage, or by some unknown loss or waste.

Notwithstanding this low rate and the apparently excessive waste and leakage, the water-works fund is in a healthy condition. The bonds for the old water-works were long since paid. There is in the sinking fund, for paying new bonds, more than $92 000, and there is a surplus in hand of more than $20 000.

The writer prepared this paper solely for the benefit of the Profession and the City of Parkersburg, and wishes again to express his appreciation to those who have discussed it, and especially to Mr. Burgess for the data furnished, and to Mr. Potter for his discussion of the *Bacillus coli* and other remarks.

It now appears that the Parkersburg filters will probably be a success; but should the future develop any surprises, there may be a question as to whether such results are due to an incurable defect in design, or otherwise.

Paper No. 1396

MULTIPLE-ARCH DAMS ON RUSH CREEK, CALIFORNIA*

By L. R. Jorgensen, M. Am. Soc. C. E.

With Discussion by Messrs. F. O. Blackwell, A. D. Flinn, F. W. Scheidenhelm, Edward Wegmann, Walter J. Douglas, Edwin Duryea, L. H. Nishkian, Gardner S. Williams, George W. Howson, and L. R. Jorgensen.

Synopsis.

This paper describes the design and construction of two multiple-arch dams built during the summers of 1915 and 1916. The determination of span length is first discussed, followed by general rules for the selection of the angle subtended by the individual arches. It is pointed out how the arch slope affects the load distribution on the arches, and the stability of the buttresses. Stress diagrams for the arches and buttresses are given, most of the calculations being graphical. The increase in deformation of concrete under sustained load, and its effect on stresses due to temperature changes is brought out, and an attempt is made to show that the time factor (time interval between the occurrence of maximum and minimum temperature) can to some extent be depended on to prevent or minimize temperature cracks. To stiffen the buttresses, counterforts are used in connection with struts. Test results of the concrete as used are given. Compression specimens were made in the field, and aged there, not under

* Presented at the meeting of April 18th, 1917.

laboratory conditions, but out in the open dry atmosphere. The up-stream faces of the arches were covered with a 1:2 coat of cement and sand, applied with a cement gun. In conclusion, some cost data are presented.

Introduction.

During the last few years several multiple-arch dams have been built in the United States, and, thus far, have been very successful in operation. Undoubtedly, many more would have been constructed had a thorough knowledge of their design and construction been more general among dam-building engineers. There are places where rock or earth fill dams, or a combination of the two, are now built, where multiple-arch dams could have been constructed more economically, and they would have been more substantial.

Although, under ordinary conditions, a rock or earth fill dam can be constructed with a sufficient, although unknown, factor of safety, such dams are absolutely unsafe under abnormal conditions, such as when water accidentally passes over the crest. It is a well-known fact that nearly all failures have been due to this cause. Water passing over the crest of a multiple-arch dam would not destroy it, and, for a more or less limited time, would not hurt the foundation, if this was otherwise at all safe for such a structure. A multiple-arch dam requires a good foundation, as the load is concentrated on the buttresses, and settlement of these would be likely to cause the collapse of adjoining arches. Whenever the foundation is solid rock, however, a multiple-arch dam can be constructed and will be as substantial as any, and more substantial than most types. The stresses and dimensions can be calculated with great accuracy. The factor of safety of such a structure, therefore, is known within narrow limits, assuming first-class construction, and on that account, precedents should not be given so much consideration as with rock and earth fill dams. These latter cannot be subjected to calculation of stresses, and therefore have to be built mostly along lines dictated by precedents. In general, it can be said that a multiple-arch dam of small and medium height (less than 100 ft. high) will cost less to construct than a rock fill dam, especially if the latter is provided with something better than a wooden up-stream face for the water-tight cut-off. Perhaps only in rare cases would there be occasion for comparing the relative costs of a multiple-

arch and a strictly earth fill dam, because, if there is enough suitable earth to construct an earth dam, a sufficiently good foundation for a multiple-arch dam and sufficient good building material for such a dam are not likely to be found at the same place, and *vice versa*.

For a multiple-arch dam higher than, say, 130 ft., the quantity of building material required, and therefore the cost of such a structure, increases quite rapidly, due mainly to the fact that the buttresses become very large and require more bracing. Eventually, therefore, a limit of height is reached, where it will be more economical to build a single arch across the canyon, unless the latter is very wide. This limit of height for any dam can only be found by trying all the types possible of application, as the shape of the dam site has also quite an influence on the design.

The Design of the Multiple-Arch Dam.

The first thing to be determined is the length of each individual span. Unless there should be strong reasons for using different span lengths for the several arches making up the complete structure, all spans should be the same, in order to facilitate the form work. Theoretically, the shorter the spans, the less the material required for the arches. The material required for the buttresses remains theoretically the same, no matter what length of span is chosen. Although a dam consisting of small spans takes less material than one where the spans are larger, the cost of construction may not necessarily be less. The form work becomes more extensive, and it is more difficult to place the concrete and reinforcing steel in the resulting narrow space between the form boards than in a wider space. Thin arch walls are more likely to collapse than thicker ones, and thin buttresses would require elaborate bracing in order to prevent their collapse long before their crushing strength had been reached. It is the arch that holds the water back, and therefore the water-tightness of the dam is to some extent a function of the thickness of this wall, although, to a much larger extent, it depends on the quality of the building material (concrete) used.

Taking all these facts into consideration, it may be stated that the practical and most economical span lies between the limits of 30 and 50 ft. For high dams, the economical span is near the upper limit; for low dams, it is near the lower limit. A 40-ft. span would be a

good average value for ordinary cases, and is chosen in the present instance.

The next feature to be determined is the length of the up-stream radius. It is known that the most economical arch* is the one that subtends an angle of 133½°, and that, for variations of about 10% on each side of this angle, the difference in economy is very small. For the dams to be described later the subtended central angle at the up-stream face is 120°, or, to be exact, 119° 57′. The volume of the arch has thereby been increased approximately 1% above the theoretical minimum, but, at the same time, the thickness has been increased 6%, thereby decreasing the ratio of thickness of arch to length of arch, which, for structural reasons, is a desirable feature, at least toward the crest where the thickness is small compared with the length. This also decreases the probability of percolation by decreasing the area of the wetted surface, and by increasing the thickness of the wall.

With the subtended angle (120°) and the span (40 ft.) decided, the length of the up-stream radius is calculated to be 23.1 ft. To facilitate form work, the length of this radius is kept constant from crest to foundation, except as noted later. Incidentally, this gives also the most economical arch, as the subtended angle is thereby kept practically constant. The arch is given a slope with the horizontal of 50°, in order that the water pressure, acting on the vertical projection of this slope, may tend to cut down the shearing stress on the buttresses to zero, or to some insignificant value.

The arch carries the total water load and a large part of the load due to its own weight. A preliminary arch thickness may be found by the simple formula,

$$P \times R_u = q \times t \qquad (1)$$

in which P equals the water pressure, in pounds per square foot; R_u equals the length of the up-stream radius, in feet; q equals the average stress, in pounds per square foot, of the area of the dam section under consideration; and t equals the thickness of the dam, in feet, at any given horizontal elevation.†

* Further information in reference to this may be found in *Transactions*, Am. Soc. C. E., Vol. LXXVIII, Paper No. 1322, pp. 689–690.

† The thickness of any horizontal arch slice (elliptical with major axis = $\frac{R_u}{\sin. 50°}$, and with minor axis = R_u) is made constant from abutment to abutment, and therefore the circular arch perpendicular to the slope must have its thickness increase from the crown toward the abutments.

After the thickness, t, has been determined, at as many points as thought necessary, say every 10 ft. apart in elevation, the weight of the arch can be calculated and the additional arch stress due to this load determined. If the total stress is found to be excessive, a new thickness will have to be chosen.

Due to the inclination of the arch, the water pressure is not distributed uniformly between the crown and the abutments on any imaginary arch slice perpendicular to the slope. As the crown is at a higher elevation, it sustains less water pressure than corresponding points at the abutments.

For the case under consideration—where the length of the upstream radius is 23.1 ft.; the subtended angle is 120°; and the inclination of the arch is 50° with the horizontal and 40° with the vertical—a point at the crown will always be

$$\frac{R_u}{2} \times \text{sin. } 40° = 11.55 \times 0.64379 = 7.424 \text{ ft.}$$

above a corresponding point at the springing line. Toward the crest this difference in elevation makes a large difference in the distribution of the load on the face of the arch, and therefore, also, in the location of the line of pressure in the arch ring. Take, for instance, an arch slice 1 ft. wide, with the middle of the crown at Elevation 5, and with the middle of this slice at the springing line at Elevation $5 + 7.424 =$ Elevation 12.424. With reservoir full to the crest, the water load at the middle point of the crown would correspond to $5 \times 62.5 = 312.5$ lb. per sq. ft., whereas the water pressure at the corresponding point at the springing line would correspond to $12.424 \times 62.5 = 776.5$ lb., or nearly 2.5 times more than at the crown.

At lower elevations this large difference (2.5 times) rapidly grows less, and becomes unimportant with crown elevations below Elevation 15. In the upper portion of the dam the radial component of the arch weight borne directly by the arch itself tends to neutralize the large difference in water pressure between the crown and the corresponding abutment points, as this weight component has its largest value at the crown, and its smallest value at the abutments. This can be shown most clearly by a graphical method, and in Figs. 1 and 2, two arch slices are drawn, each assumed to be 1 ft. wide. In Fig. 1 the middle of the crown is at Elevation 5, and then a width of 6 in. is taken on each side; and in Fig. 2 the crown is at Elevation 10. The

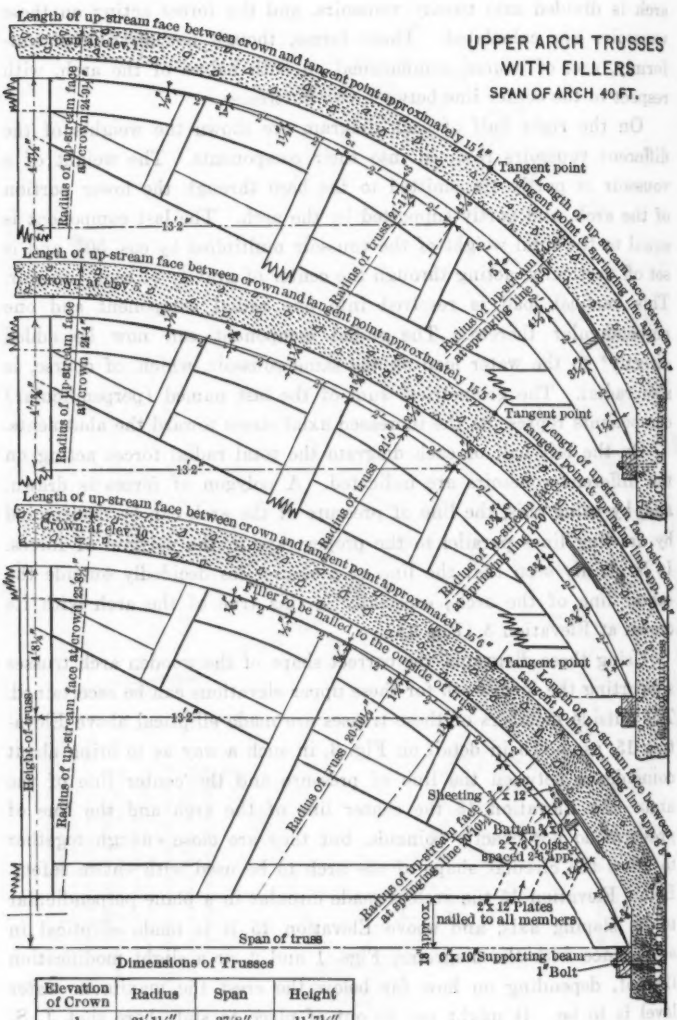
FIG. 2.



arch is divided into twenty voussoirs, and the forces acting on these voussoirs are calculated. These forces, though not distributed uniformly, are, of course, symmetrical on both halves of the arch, with respect to the center line between two buttresses.

On the right half of each diagram are shown the weights of the different voussoirs resolved into their components. The weight of a voussoir is partly transmitted to the base through the lower portion of the arch, and partly supported by the arch. The last component is equal to the total weight of the voussoir multiplied by cos. 50°, and is set off vertically, acting through the center of gravity of each voussoir. This vertical load is resolved into one radial component and one perpendicular thereto. The radial component can now be added directly* to the water load on the same voussoir, which, of course, is also radial. The geometrical sum of the last named (perpendicular) components represents the increased axial stress toward the abutments.

On the left half of each diagram the total radial forces acting on the different voussoirs are indicated. A polygon of forces is drawn, and, by using this, the line of pressure of the arch can be determined by drawing lines parallel to the proper rays in the polygon of forces. It is plainly seen that the line of pressure lies decidedly outside the center line of the arch; especially is this true of the arch with its crown at Elevation 5 (Fig. 1).

Using these diagrams, the correct shape of the wooden arch trusses supporting the form work for these upper elevations can be ascertained. The outside members of these trusses are made elliptical above Elevation 15, as shown in detail on Fig. 3, in such a way as to bring about coincidence between the line of pressure and the center line of the arch. At Elevation 15 the center line of the arch and the line of pressure do not exactly coincide, but they are close enough together to allow the circular shape of the arch to be used with entire safety. Below Elevation 15 the arch is made circular in a plane perpendicular to its sloping axis, and above Elevation 15 it is made elliptical in accordance with the diagrams, Figs. 1 and 2, or a slight modification thereof, depending on how far below the crest the maximum water level is to be. It might not be out of place to state here that J. S.

* For greater accuracy, this force should be multiplied by the ratio, $\frac{\text{length of mean radius}}{\text{length of up-stream radius}}$. It has been neglected in the present case, as this ratio is very close to unity.

FIG. 3.

Eastwood, M. Am. Soc. C. E., who has been very prominent in bringing into actual use the multiple-arch type of dam, builds the top portion of the arches vertical, whereby the circular shape can be used for the entire arch.

Stresses Due to Temperature Changes.

As dams are generally built during the summer season, it is only logical to assume that after their completion the individual arches are under tensile stress most of the time when the reservoir is empty, and decidedly so if it is empty during the cold season. The reinforcement in the arch, therefore, has been placed with the sole purpose of taking up these tensile stresses, which reach their maximum value near the down-stream face at the crown, and near the up-stream face at the abutments, under the conditions just stated. From the drawing at the left of Fig. 4 it will be seen that the reinforcing steel is placed at a distance equal to one-fourth of the total arch depth from the respective faces subject to tensile stresses, at the crown and at the abutments. The quantity of steel in the arch is perhaps not entirely sufficient to take care of the maximum condition of temperature drop, but it is believed that if tension cracks develop, the presence of the reinforcement will cause them to be minute and well distributed, and that, when the structure becomes loaded, the cracks will close tight. It was not deemed advisable to put in the arches more steel than that shown by Fig. 4, for the reason that it is of comparatively little use when the reservoir is full. It was also kept in mind that a large change in temperature is not likely to occur suddenly, as a time element of perhaps weeks or months is generally interposed between the occurrence of maximum and minimum temperature in a dam body. This time factor can be depended on, to some extent, to prevent or minimize temperature cracks. It gives the modulus of elasticity time to adjust itself to the new condition (colder or warmer concrete).*

The Stability.

After the buttresses have been given some preliminary dimensions, the stability of the whole structure can be investigated, most con-

* That the deformation of concrete increases, under sustained load, has been shown by tests and in practice. Two papers on the subject were read at the Twelfth Annual Convention of the American Concrete Institute, in Chicago, one by A. H. Fuller, M. Am. Soc. C. E., and C. C. More, Assoc. M. Am. Soc. C. E., entitled "Tests Showing Continued Deformation under Constant Load", and one by Mr. Carl B. Smith entitled, "The Flow of Concrete Under Restrained Load". This was abstracted in the *Engineering Record*, March 4th, 1916, p. 329. See also "The University of Minnesota Studies in Engineering, No. 3", by F. R. McMillan.

veniently by a graphical method, as shown by Fig. 6, representing a section through the crown of the arch. To facilitate the investigation, the dam is divided into horizontal sections, 10 ft. apart in elevation, and the forces acting on and above each section are shown to scale in the location and direction in which they act.

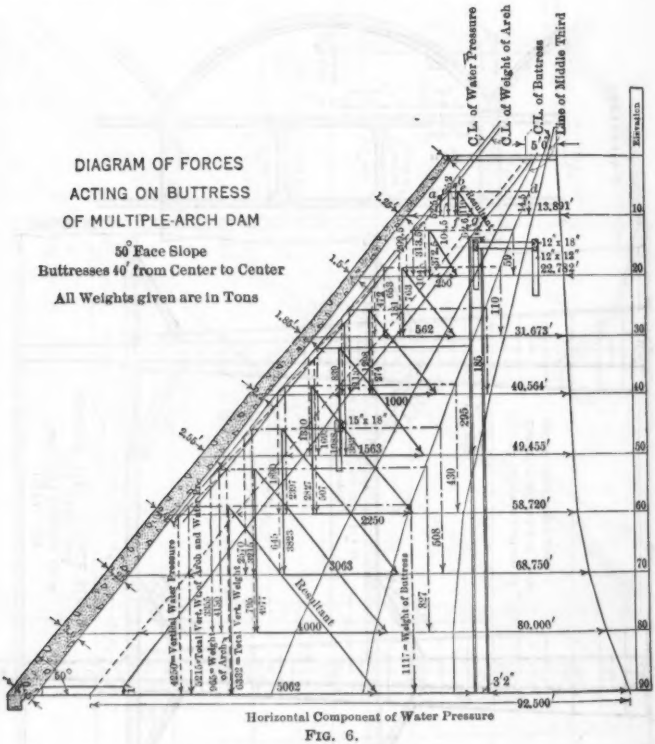

FIG. 6.

The most important force acting on the structure is the water pressure, and this, as usual, is assumed to be concentrated in a horizontal plane which is two-thirds of the total depth below the water surface.

The horizontal plane in which the water pressure is assumed to be concentrated intersects the up-stream face along an elliptical curve. The point of application of a single force, representing the water pressure on one total span of 40 ft., coincides with the center of gravity of

this ellipse, at least, as long as the water pressure does not penetrate the up-stream face skin, such as plastering, etc.

Due to the fact that the arches have been given a slope of 50° with the horizontal, the water pressure will have a vertical component $= \frac{\text{horizontal component}}{\text{tan. } 50°}$. To a very great extent, the stability of the dam depends on the presence and action of this component, as it tends to hold the structure firmly down on its foundation.

The point of application of the water pressure, as already stated, is taken at the center of gravity of the ellipse. From the crown this is a little more than one-third of the total distance $\left(\frac{1}{3} + 5\%\right.$ for present conditions) between the crown and the springing line.

Considering first the upper 10 ft. of the dam, the horizontal plane in which the water pressure can be assumed to be concentrated is at a distance of $\frac{2}{3} \times 10$ from Elevation 0 downward, with the water surface at Elevation 0, and the point of application, a, of the single force is

$$\left(\frac{1}{3} + \frac{5}{100}\right) \frac{11.55}{\text{sin. } 50°} = 5.78 \text{ ft.}$$

from the crown, measured horizontally.

The horizontal water pressure due to the 10 ft. of water on the 40-ft. span is

$$\frac{0 + 625}{2} \times 10 \times 40 = 125\,000 \text{ lb., or } 62.5 \text{ tons.}$$

The vertical water pressure is equal to $\frac{62.5}{\text{tan. } 50°} = 52.5$ tons. This latter force is now combined with the portion of the weight of the arch acting vertically. The weight of the arch above Elevation 10 is equal to its volume in cubic feet multiplied by the weight of 1 cu. ft. The center of gravity of the section—a trapezoid—is found, and the center of gravity, b, of the whole arch is then taken to coincide with the center of gravity of an ellipse through the center of gravity of the section, in the same manner as explained previously for the water pressure. The weight of the arch is now combined with the vertical component of the water pressure, and the location of their resultant is found by taking moments around either point, a or b. The numerical value of the resultant is equal to the sum of the two forces, $52 + 52.5 = 104.5$ tons. Taking moments around the point, a, and scaling the distances,

preferably on the sloping line between a and b for greater accuracy, we have the equation $\frac{52 \times 2.75}{104.5} = x = 1.367$ ft., giving the location of the resultant at a point 1.367 ft. from a along the line between a and b. The weight of the buttresses (above Elevation 10) assumed to be concentrated in the center of gravity, d, is calculated to be 14.5 tons; it is combined with the vertical load of 104.5 tons on the arch, in the same manner as shown previously, by taking moments around any point, say c. The location of the resultant is found to be at e, and its value is $104.5 + 14.5 = 119$ tons. This represents the total vertical force, both as to size and location.

This force is now combined with the horizontal water pressure of 62.5 tons, and the resultant is drawn. It is the purpose of this diagram, Fig. 6, to give the value of the resultant of all forces, and to establish the point of intersection, g, between this resultant and the base, in this case at Elevation 10. For convenience, the distance from e to f, representing the total vertical force of 119 tons, may be measured, and the distance, f-g, representing the 62.5 tons horizontal water pressure, may be set off on the base to the same scale.

Consider next the portion of the dam above Elevation 20 as a whole. The place of application of the concentrated water pressure is at a distance of $\frac{2}{3} \times 20$ ft. below Elevation 0, and the point of application of a single force representing the water pressure on the 40-ft. span is located the same as before, 5.78 ft. from the crown toward the springing line, measured horizontally. The vertical component of the water pressure $= \frac{\text{horizontal component}}{\text{tan. } 50°}$, acting on the arch between Elevations 0 and 20, is now combined with the weight of the arch lying between Elevations 0 and 20, and their resultant is drawn in the correct location, found by taking moments as shown previously. This resultant is again combined with the weight of the portion of the buttress lying between Elevations 0 and 20. The shape of the buttress is taken as that of an obelisk, and its volume and the location of the center of gravity are found from ordinary rules applying to such bodies. The weight of the struts and counterforts is to be added to the weight of the buttress, whereby the location of the center of gravity might be slightly changed.

The resultant of all vertical forces acting on the dam above Elevation 20 can now be found, both as to size and location, and combined with the horizontal water pressure, whereby the point of intersection of the resultant with the base at Elevation 20 is determined.

The same method of procedure is followed for the remaining portion of the dam, each time taking the base 10 ft. lower than in the preceding calculations, and the whole diagram, Fig. 6, is completed. If, now, the center line of the buttress, and also the two lines representing the middle thirds, are drawn, this diagram will point out very clearly whether or not the load is distributed economically on the buttress. For maximum economy, the resultant of all forces should intersect the base in the center line of the buttress; then the load will be distributed uniformly over the whole base. Toward the top this is not quite possible, and is not important, as the material there cannot be stressed very highly at any rate; but, toward lower elevations, the down-stream slope of the buttress should be shaped so as to conform with this condition, *viz.*, the resultant intersecting the base in the center line, or approximately in the center line, of the buttress. The total vertical load on the section shown in Fig. 6 is seen to be 6 332 tons, and the horizontal water pressure, 5 062 tons, both on a 40-ft. span. If the coefficient of friction is taken at 0.75, it is seen that the actual shear along the base amounts to only $5\,062 - 6\,332 \times 0.75 = 313$ tons. There is considerable steel in the section to help take up this shear, and therefore it was not deemed necessary to eliminate the shear entirely. There is no hydrostatic uplift to amount to anything acting on a dam of this type, and water could hardly find its way to lubricate the surfaces of possible cracks in the buttresses. Wherever it would be desirable to eliminate the shear entirely, the face slope should be made flatter, say 45, instead of 50 degrees. This, of course, adds to the material required for construction, but is the cheapest and best way of accomplishing the result.

Some difference of opinion may well exist as to the actual stress per square unit of area of the buttress at any horizontal elevation. The loads per buttress are given on Fig. 6. For instance, at Elevation 80, the vertical load is seen to be 4 977 tons, and the horizontal load, 4 000 tons. As the horizontal area is 360 sq. ft., the unit vertical stress should be $\frac{4\,977}{360} = 13.82$ tons per sq. ft., or 192 lb. per sq. in. The

shear would be a little more than friction alone would take care of, but steel is provided for the remainder. The resultant of the two forces (horizontal and vertical) intersects the base 2 ft. down stream relative to the center line, but on account of having the counterfort (20 sq. ft.) on this side of the center line also, the stress is actually distributed uniformly. Now, if, instead of the two principal forces, their resultant is used, assuming it as acting on a number of steps perpendicular to the direction of this force (the resultant), the apparent unit stress will be much higher. Thus, the resultant (6 385 tons) acting on an area equal to the sum of all the steps (360 $\times$ sin. 51° 13′ = 280 sq. ft.) will produce a compression equal to $\frac{6\,385}{280} = 22.8$ tons per sq. ft., or 317 lb. per sq. in.

There is a great difference between 192 and 317 lb. per sq. in. The actual unit compression will be somewhere between, undoubtedly depending on the relative value of the modulus of elasticity of the concrete for compression and for shear. It is seen that the first method, using the principal forces, gives the maximum possible shear that could occur, and that the other method gives the maximum possible unit compression that could occur. None of these methods is very satisfactory, as none fixes the absolute value of stress within narrow enough limits, but the writer knows of no better at present.

The reinforcing steel embedded in the buttress is put there for different purposes. Along the up-stream slope, the triangular steel construction shown in Figs. 4 and 5 ties the adjacent arches into the buttress. This is desirable on account of the fact that, in order to facilitate construction, the buttresses are built first, and the arches later. The hooping that interconnects the different bars is simply left protruding through the concrete of the buttress at the time this is built. Should one arch fail, this triangular girder would immediately take up the unbalanced thrust and prevent adjacent arches from collapsing, and this is its principal duty. Besides this, however, the steel is active in preventing cracks in the buttress and in taking up some shear. Toward the down-stream edge of the buttress, four vertical rods are embedded in the concrete for the purpose of stiffening it, preventing cracks, and taking care of wind pressure. Toward the middle portion, reinforced counterforts are constructed for the same purpose. These are still more effective in accomplishing this, due to

the greater distance between the pairs of steel rods. All material in the counterforts supports load the same as the buttress itself, but the counterforts, at the same time, are most effective in stiffening the large flat slab (buttress) so that fewer struts are required.

Toward the top of the buttress (at Elevation 15) two horizontal struts are tied to the vertical reinforcement (Figs. 4 and 5). These two struts are designed so that, besides their main purpose of holding the upper portion of the buttress in place, they are capable of supporting a light roadway. At Elevation 45 another strut is placed near the up-stream face, mainly in order to support the triangular girder, should the latter ever be required to support any unbalanced arch pressure. All struts are able to withstand tension as well as compression, as can be judged from an inspection of the details on Figs. 4 and 5.

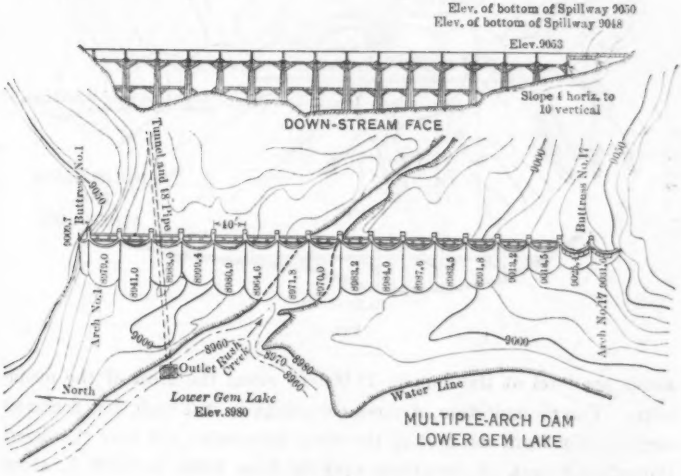

FIG. 7.

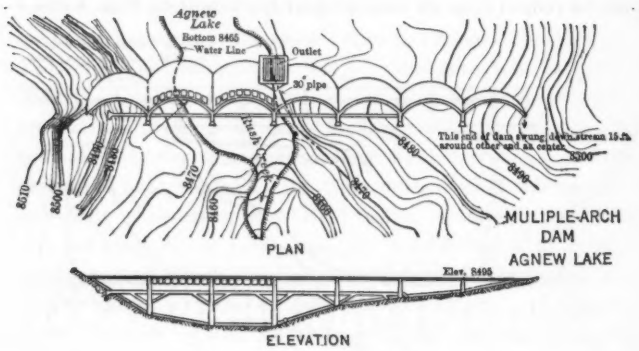
GEM AND AGNEW LAKE DAMS.

The design shown in the foregoing illustrations was made by the writer for the Pacific Power Corporation, of Bodie, Cal., to be used for the construction of their Gem and Agnew Lake Dams, on Rush Creek, Mono County, California. Fig. 7 is a plan of the Gem Lake Dam and dam site, and Fig. 8 shows the Agnew Lake dam site. On Fig. 7 is also indicated the outlet works, consisting of a concrete

chamber provided with a row of iron bars in front, and a 48-in. steel pipe laid through a tunnel for about 300 ft. This pipe line terminates in a power-house 1 808 ft. below (in elevation) the top contour of the lake. The maximum height of any individual arch of this dam is 84 ft., and the vertical distance from the deepest point in the foundation to the crest is 112 ft. The length across the dam site at the crest (Elevation 9 053) is 700 ft. The reservoir created has a capacity of 17 000 acre-ft., and is capable of regulating Rush Creek to yield an estimated average flow of 45 sec-ft. The drainage area above the dam is 22½ sq. miles, and is on the eastern slope of the Sierra Nevada Mountains. Its elevation ranges from 9 000 ft.



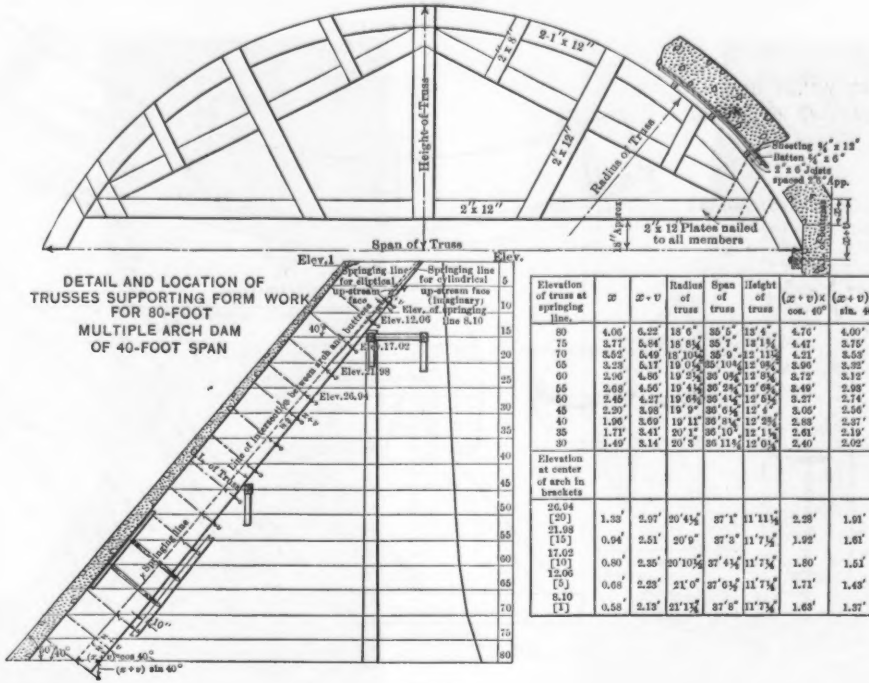


FIG. 8.

above sea level at the dam to 12 000 ft. along the crest of the mountains. The precipitation at these elevations is still high, but decreases very rapidly from the foot of the steep mountains out over the desert immediately east, at elevations ranging from 6 000 to 7 000 ft. above sea level.

The rock at the dam site, for the most part, was exposed bed-rock worn clean by glacial action. Some excavation, however, was necessary in the stream bed and through a rock slide at the north abutment. The building material for the dam was found near-by. The sand was taken from the shore of the natural lake. The rock had to be hauled a short distance on a tramway, first from the outlet tunnel dump (limestone), and later from a large rock slide (granite) about

2 500 ft. away. All available materials in the neighborhood, especially the different sand deposits, were tested before any particular material was selected for construction. As the sand deposit along the shore of Gem Lake was good, it was used. This sand was first pumped, and later shoveled, from the lake, and transported to a storage pile near the mixing plant. This lake sand, which contained 3½% of clay and 1% of dirt, was mixed with the sand from the rock crusher (all particles being less than ¼ in. in diameter) in the proportion of about three-fourths of lake sand to one-fourth of crushed rock sand. This gave a very good combination, both as to strength and watertightness.

Compression tests on 6-in. cylinders were made as the work progressed, using Bear brand Portland cement, Gem Lake sand, and crushed rock, in the proportions 1:2:4, and averaged about 900 lb. per sq. in. for crushing at the age of 14 days.

A 1:2:4 mix was adopted for the arches and struts, and a 1:2½:5 mix for the buttresses. The actual proportions, however, were sometimes changed, but 1½ bbl. of cement for the arches, and 1¼ bbl. for the buttresses were used always. The rock was crushed in a gyratory crusher, and separated into three sizes through a revolving screen having 1½, ¾, and ¼-in. meshes. The rejects from the screen went into a jaw crusher, the jaws of which were set to give a maximum size of 2 in.

The distribution of the concrete to the different arches and buttresses was done with two-wheeled push carts and short chutes.

During the construction period, in the summers of 1915 and 1916, tension tests were made of cement briquettes in a small field laboratory. Much attention was also paid to the sand used, and 1:2 and 1:3 mortar briquettes were tested frequently; silt analyses were made as the work progressed.

The reinforcement placed in the dam consisted of high-carbon steel bars, either corrugated or twisted. As the position and details of these bars are fully shown in the figures, no further explanation need be given.

The trees standing on the reservoir site were cut down, sawed into lumber in a mill erected on the ground by the contractors, and used for the forms. Large cone-bearing trees can be found in this neighborhood up to Elevation 11 000 in fairly large quantities, but

not of the best quality. The lumber proved to be good enough for form work, was used green, and on that account ¾ by 4-in. battens were placed on the under side of the sloping arch to prevent the leakage of grout between the boards when shrinkage took place. These battens also helped to give an even, circular shape to the outer ¾ by 12-in. boards, constituting the form for the down-stream face. This sheeting was supported on 2 by 6-in. studs, 2 ft. 6 in. apart, toe-nailed to the wooden arch trusses shown in Figs. 3 and 9. These trusses were 5 ft. apart in elevation, and a little more than 6½ ft. apart, measured along the arch slope. The form work for the up-stream face consisted also of ¾ by 12-in. boards nailed to 2 by 6-in. studs, which in turn were nailed to circular boards at regular intervals. This outside form was held away from the inside form (down-stream side) by wooden distance pieces of the proper length, which pieces were removed just before the concrete reached them.

A 1:2 plaster coat of cement mortar ¼ in. thick at the crest, and increasing to ¾ in. thick 80 ft. below, was put on the up-stream face with a cement gun.

At the south abutment the two last arches are provided with spillway openings. These spillway openings can be closed with loose flash-boards. This it is proposed to do toward the end of the wet season, so as to fill the reservoir to within, say 1 ft. of the crest of the dam, thereby gaining 2 ft. of water over an area of nearly 300 acres. The spillway is shown in detail on Fig. 10.

Cost.

The Gem Lake Dam contains 8 537 cu. yd. of concrete and 82 tons of reinforcing steel. The contract price was $22 per cu. yd., including cement, forms, plastering the up-stream face, and all tools and materials except the reinforcing steel, which was paid for as an extra at the rate of $110 per ton in place. The excavation, of which there was only a limited quantity, was also paid for as an extra. The high cost is explained by the fact that freight rates were high, and, further, that the distance from the railroad to the power-house site at Silver Lake, at the foot of the steep mountains, was nearly 60 miles over desert roads with heavy grades. From the power-house site, a tramway, approximately 4 500 ft. long, took all supplies up the mountain side to Agnew Lake, 1 250 ft. above. At the outlet of this lake, the

Agnew Dam, a smaller structure, 30 ft. high and 280 ft. long, similar in design to the Gem Lake Dam, but having only one strut, was built at the same time and at the same unit prices, in order to increase the capacity of the natural lake. All material for use in the construction of the Gem Lake Dam was brought across this lake on a barge, for a distance of about 2 000 ft., to the foot of another tramway terminating at the site of the Gem Lake Dam, 550 ft. higher in elevation. The cost of these tramways was not included in the price per cubic yard for concrete, but was paid for as an extra. These tramways were also necessary for the construction of the pressure pipes to the power-house, one from Gem Lake, and one from Agnew Lake, and would have had to be built independent of the dams.

For the long haul across the desert from the Southern Pacific Railroad station at Benton, Cal., to the power-house at Silver Lake, six 75-h.p. C. L. Best tracklayers, burning distillate, were used, each hauling three trailers. The net load was as close to 20 tons as practicable, and the time necessary to make one round trip was about 6 days of 12 hours, including loading, unloading, and ordinary delays. The speed per hour of these tracklayers was 2½ miles on high gear, and 1½ miles on low gear. The contractors found that the cost to them for hauling this distance was at the rate of $13.50 per ton. The hauling of the cement and materials for the dams was not paid for extra, but included in the price for concrete in place.

A rock fill dam on the same site would have had to be built for $2.15 per cu. yd. (construction cost), including the water-tight face and hand-laid rock, in order to be on equal terms, as to cost, with the multiple-arch dam built. In the writer's opinion, this would not have been possible in this place. In any locality where cement can be laid down at less cost than in this case, the relative cost of a multiple-arch dam and a rock fill dam will be still more in favor of the multiple-arch dam.

The writer furnished the designs and also supervised the construction of the dams.

Mr. C. O. Poole was Chief Engineer for the whole development, E. J. Waugh, Assoc. M. Am. Soc. C. E., was Resident Engineer, L. B. Curtis, M. Am. Soc. C. E., Field Engineer, and Mr. F. O. Dolson, Superintendent of Construction.

Messrs. Duncanson Harrelson Company, of San Francisco, were the contractors for both dams.

DISCUSSION

Mr. Blackwell.

F. O. BLACKWELL,* M. AM. SOC. C. E.—This paper is a valuable contribution to the theory of multiple-arch dam design, particularly as to the economical spacing of the piers and the thickness of the arch. The dam sites are on small drainage areas, high in the mountains, where labor and materials are very expensive. It has been stated† that the cement for these dams cost $7.50 per bbl.

A very conservative design might have been prohibitive in cost, and probably the region is uninhabited and no damage to life or property would result in case of failure.

The sections appear to be very thin for a 40-ft. span, and the reinforcement is extremely light. The use of more concrete would have added much to the ability of the structure to resist unexpected floods, ice thrust, changes of temperature, etc.

It is always desirable, too, to have a good margin over theoretical quantities in order to allow for poor material and workmanship, which will occasionally be found, no matter how careful the engineeer may be.

A fair comparison between this dam and other types is difficult to make, as the standards are quite different, but the multiple-arch appears to be cheaper than any other kind under the conditions which existed at the location, except possibly a rock fill with a thin vertical core-wall. The author states that there was loose rock but no earth at the sites.

The usual type of solid, retaining-section, gravity dam would have required about four times as much concrete as was used in the dam as built, but from 25 to 40% of cheap rock might have been laid in thick concrete sections, and concrete containing less cement might have been used. The form work and cost of forms and placing would also be less in a large mass.

Including engineering and overhead expenses, the multiple-arch dam probably cost about $30 per cu. yd., so that a gravity dam would have to be built for $7.50 per cu. yd. in order to equal it in cost.

In an accessible location, and with concrete rubble masonry at from $3 to $4 per cu. yd., the solid dam, in the speaker's experience, has always figured out to be cheaper than any multiple-arch or reinforced design.

Compared with a reinforced concrete slab dam, the multiple-arch seems to have the advantage in cost. The piers would have to be twice as many, the deck thicker, and the reinforcing metal in the deck about ten times as great.

---

* New York City.

† In an article in *Engineering News*.

Mr. Blackwell.

One of the principal objections to a multiple-arch is the fact that the sections are all dependent on each other for stability. If one pier should settle, the arches on each side of it would break, and, as there is nothing to take the thrust of the remaining arches, they would push over their piers, and the whole dam would collapse. The struts between the piers could not be relied on to save the dam from complete failure, as the movement of any pier would throw them out of line and cause a resultant thrust, tending to push the pier in the direction in which it had already started to move. Rigid foundations, such as the author states exist in this case, are essential.

The Great Western Power Company started to build a multiple-arch dam at Great Meadows, on the Feather River, California, but abandoned it in favor of a rock fill with an earth face sluiced into place on the up-stream side to make it water-tight and cover the bottom for a considerable distance up stream. The lava foundations, on being opened up, were found to contain mud seams, which might have moved under the piers. As a general principle, a dam should be no better than its foundations. On a yielding bottom a dam of a flexible type is required.

There is one important matter that Mr. Jorgensen does not mention: At an altitude of 9 000 ft. in the Sierras it must be very cold at times, and thick ice must form in the reservoir. The thin arch is not much protection against cold, ice must form to a considerable thickness on the face of the dam, and such cracks as develop will be filled with ice. There may also be ice thrust against the dam, which could have serious results. With a mass of ice frozen fast to the arches, the inclination of the face would not relieve this pressure. Floating masses of ice may also drift against the arches, thus causing concentrated pressures on parts of the dam, and the arches are not designed to stand unbalanced pressures. One advantage of the ordinary form of masonry dam is the weight of its large mass, which will stand considerable impact without damage.

The spillway does not look very large, and would be likely to be choked with floating ice, in which case the water would go over the top of the arches. If this occurred, and the water carried ice with it, the ice would fall on the struts between the piers and might damage them. A deck on top of the dam would carry the water so that it would fall below the dam and not injure the struts and the foundations. It would also strengthen the top of the arch against ice thrust and would tie the piers together better.

A pressure of nearly 23 tons per sq. ft. seems to be extreme for a practically unreinforced and slender pier 90 ft. high.

The coefficient of friction against sliding on the foundations is 0.80 as compared with 0.65 in most solid dam designs. If the rock were smooth or horizontally stratified this might be unsafe.

Mr. Blackwell. It would be very interesting to hear from the author as to whether there has been any leakage through the arches, or whether any trouble has been experienced from ice.

Mr. Flinn. A. D. FLINN,* M. AM. SOC. C. E.—Minimizing the quantity of masonry to be used in a dam naturally occurs to any one who has given much thought to the design of large masonry dams. The idea of accomplishing this by arches and buttresses seems to have occurred to engineers in different parts of the world many years ago, for such dams have been built in India and Australia, as well as in America. They have sometimes been called buttressed dams. There appear to be three important varieties: One, of which the Meer Alum Dam in India is an example, has the arches vertical, with the buttresses sloping on their down-stream sides or faces; a second variety is similar, but has the spandrel spaces filled with masonry; and the third variety, to which the dams described in the paper belong, has the arches inclined, with the down-stream faces of the buttresses vertical, or nearly so.

Mr. Blackwell has referred to the disadvantages of thin sections in such structures. The speaker would like to emphasize that point, on the basis of some experiences with concrete within the last few years. Possibly, some other engineers have also had experiences showing that Portland cement concrete under certain conditions disintegrates when exposed to weather, and particularly when exposed to weather and water together. The cause for such disintegration is not yet fully known, but it seems to be due in part to abuse of the concrete (or rather of the cement in it) by the use of excessive quantities of water in mixing, and leaving it in the concrete when it is finally placed in the forms. The speaker knows of one or two cases in which disintegration, apparently due to this cause, has gone on rapidly. Therefore, it is quite evident that a structure like a dam, with walls as thin as 12 to 24 in., would not long resist such an attack, if it should set in.

Another question—one of economy—has occurred to the speaker. In the East, dam sites are usually overlaid with glacial drift or other earthy deposit to considerable depths. Rarely does one find the nearly exposed rock foundations with which the West is favored in many places. It would seem that digging through a considerable depth of earth for the arches and the buttresses would be a handicap to the multiple-arch dam, in comparison with the "solid" masonry dam.

Another thought which occurs to one in looking at dams of this design, is along a line on which American engineers have not directed very much attention until within the past 2 or 3 years, and that is, the vulnerability of structures to attack either by malicious persons or by an enemy. It seems to the speaker that a "hollow" dam might

* New York City.

be easily wrecked, if not guarded, in time of war, strike, or riot, and that a person of malicious intent, in the case of any such trouble, could readily do a structure of this kind great injury in a few hours, or even in a briefer time. One of the important considerations in providing for the guarding of a structure is to have it so arranged or so strong that it can be easily protected, and by the minimum number of troops. Mr. Flinn.

In comparing the three forms of multiple-arch dams which have been mentioned, the question naturally arises: What are the relative advantages between the arch set vertically with the buttresses sloping on the down-stream side, and the type of dam described in the paper, with the arches sloping and the buttresses having vertical faces on the down-stream side? Is there a distinct advantage in either case, or is the difference solely due to an endeavor to secure patent rights, or some other commercial advantage? If any variety of multiple-arch dam has advantages over the others, will not the author or some other engineer who has devoted special study to this type, state these advantages? The speaker is interested as to the readiness or difficulty of making a dam of this kind, together with its foundations, sufficiently water-tight, and what standard of water-tightness is accepted. Would the leakage permitted be greater than that from a well-built "solid" masonry dam? As time goes by, do the agencies which make for greater water-tightness prevail over those which tend to produce leaks?

F. W. SCHEIDENHELM,* M. AM. SOC. C. E.—The author has presented an interesting and detailed analysis of certain features of multiple-arch dam design in such a manner as to deserve the appreciation of the members of the Profession interested in dam design and construction. In addition to the general analysis, he has given an outline of the special features pertaining to the design and construction of the two particular multiple-arch dams at Gem Lake and Agnew Lake. Essentially, however, the paper is general in its character and, correspondingly, this discussion will also be mainly of a general nature. Mr. Scheidenhelm.

The multiple-arch dam, like the flat-deck dam, belongs to what one might call the family of hollow dams. The multiple-arch type differs from the flat-deck type (of which the Ambursen dam is the most familiar) primarily in the method of transferring the water load to the supporting buttresses. Both types involve relatively high unit costs for the concrete work required. Accordingly, they find greatest favor in situations where it is proposed to build dams of concrete, but where the cost of cement is high. The dams at Gem and Agnew Lakes are cases in point, for there the average cost of cement delivered at the site of the work is reported to have been $7.50 per bbl. Apparently, only rock-fill dams, but not solid masonry dams, were considered as alternatives for multiple-arch dams for the sites mentioned. It seems

* New York City.

Mr. Scheidenhelm.

evident, however, that, had solid masonry dams been built, the high cost of cement would have more than offset the relatively high cost of the form work required for the multiple-arch dams.

As to hollow dams, there appear to be two principal points which require careful attention, namely, the protection of reinforcing steel and the tendency to skimp the sizes of the structural members. In the first respect, the multiple-arch type has a decided advantage over the flat-deck type, in that it requires a much smaller quantity of steel. Consequently, there is so much less steel which might be placed in danger of corrosion, and it is so much the easier to protect the steel. Again, the multiple-arch dam permits the use of longer spans, say, from 20 to 50 ft. between centers of buttresses, as compared with corresponding spacings for the flat-deck type of from 15 to 30 ft.

On the other hand, the cost of form work for the multiple-arch dam is somewhat greater than that for the flat-deck type, and, what is more important, the multiple-arch dam is more susceptible to difficulties and damage in case of settlement of the footings. The arches cannot withstand as much racking as flat-deck slabs. The author points out that he provides struts to take care of the unbalanced arch thrust which would result if one or more arches or bays were to fail. Of course, a dam is intended not to fail, and, hence, one is concerned more with precautions against failure than with measures to be taken in case of failure. Even from the latter point of view, however, the value of the struts would be problematical were they, in case of failure of the corresponding arches, to be subject to the impact of floating ice, tree trunks, or other débris. Moreover, it would seem that the struts might become overloaded due to blocking the passage of such débris, and thus induce failure in lateral flexure.

After all, it appears to the speaker that, in the case of the multiple-arch dam, one must insist on unyielding foundations. Fortunately, there seems to be no deficiency in bearing value on the part of the foundations of the dams on Rush Creek.

It is not surprising to find that the use of the multiple-arch dam dates far back of that of the flat-deck type, at least in so far as the construction of the latter in reinforced concrete is concerned. The most conspicuous example is that of the Meer Alum multiple-arch dam, built in India a century or more ago. This dam, referred to by Mr. Flinn, has a height of about 45 ft., and involves astounding span lengths, varying from 70 to 147 ft. The arches are plain, and are built of brick in lime mortar. New South Wales boasts of a dam, the Belubula, in which the spandrels of the arches are filled in with masonry, thus making impossible radial action of the water pressure.

In the United States there are, perhaps, a dozen multiple-arch dams, the most familiar of which heretofore have presumably been those built under the design and direction of John S. Eastwood, M. Am. Soc. C. E. The Eastwood multiple-arch dams seem to differ from those

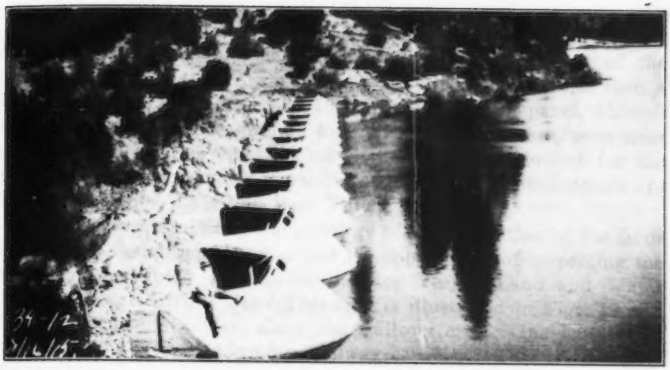

FIG. 19.—LOS VERJELS DAM, NEAR OROVILLE, CAL.

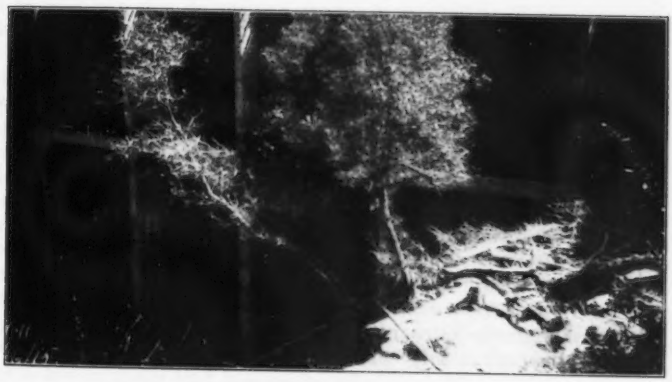

FIG. 20.—DOWN-STREAM VIEW OF LOS VERJELS DAM.

FIG. 21.—DOWN-STREAM VIEW OF NEW BIG BEAR VALLEY DAM.

designed by the author essentially as regards the treatment of the arches near the crest. Mr. Jorgensen uses an elliptical, rather than a circular, form for, say, the upper 15 ft. of each arch or panel, whereas Mr. Eastwood apparently prefers to retain circular arches, even near the crest, and, to this end, has made the arch axes vertical for the upper portions of the panels of certain of his dams. Of this design are the dams at Hume Lake and Bear Valley, California. Mr. Scheidenhelm.

The speaker has not had the privilege of visiting either of the dams described by the author, but has had the opportunity of inspecting the 60-ft. high multiple-arch dam of the Los Verjels Land and Water Company, near Oroville, Cal. This dam is illustrated in Figs. 19 and 20. The former is a view along the spillway crest. Incidentally, it emphasizes the lack of adequate spillway capacity. This is shown by the erosion which is apparent at the opposite bank.

Fig. 20, a view from down stream, shows the buttresses and bracing to be relatively slim, to such an extent, in fact, as to afford to the eye no impression of stability.

The Bear Valley Dam, Fig. 21, makes quite a contrary impression, and, though the product of the same designer, governed as he apparently was by the financial ability of the respective clients, is of pleasing appearance and proportions. Even in this case, the speaker would prefer a system of bracing between buttresses consisting of relatively deep (vertically) beams or walls. Such deeper beams would certainly afford greater stiffness, and, moreover, would tend toward a better distribution of the load on the footings. In other words, with the buttresses well braced, any deflection or settlement of the different footings would, of necessity, be practically equal, and hence the firmer, less yielding, foundation material would, as is desirable, take more load per unit of area than the less firm portions. The last-mentioned advantage of the deeper bracing beams is, to be sure, of little value in foundations where the deflection under load is inappreciable.

Turning now to the details of the paper, the speaker is inclined to think that the multiple-arch dam may properly be applied even more widely than the author claims, for he, by implication, limits its utility to locations where "the foundation is solid rock." Nevertheless, the multiple-arch dam is not entirely free from the ills of other dams. More particularly the speaker cannot agree with the general statement of the author that "there is no hydrostatic uplift to amount to anything acting on a dam of this type." Although not obsessed with such a fear of uplift pressure as is shown by some engineers, the speaker insists that the possibility, and often the certainty, of uplift pressure must be recognized.

In the absence of more definite information, the allowance made for uplift pressure must be, of necessity, a matter of judgment. Certainly, however, in the case of a foundation material which, where

Mr. Scheidenhelm.

unbroken, is impervious, but contains approximately horizontal laminations, it must be admitted that uplift pressure may exist in such laminations or seams. Under such circumstances, the effect of the uplift pressure would be practically the same as if the footings of the buttressed hollow dam were continuous, with uplift pressure existing in the plane of contact of the footings with the surface of the foundation material. Manifestly, with rock of the characteristics previously suggested, a buttressed hollow dam, such as the multiple-arch dam, has no advantage over the solid masonry dam, except to the extent that, by reason of the details of construction, it may be a simpler matter adequately to drain the underlying foundation material and thus relieve any uplift pressure.

As regards sliding, also, the speaker feels that it is unwise, and, in some instances, has been fatal, to consider a dam apart from its underlying foundation material. The foundation material, or substructure, must act as a unit with the dam body, or superstructure, if the desired object of constructing a safe dam is to be attained. The speaker does not intimate that either of the multiple-arch dams described by the author is in the least unsafe as regards either uplift pressure or sliding. However, he does feel, for instance, that it is not sufficient to aim for a safe shearing resistance at, or near, the base of a buttress, but believes that it is fully as important, and in many cases even more difficult, to design so as to obtain safe resistance to shear or to sliding within the foundation material itself at planes or laminations just below the base of the footings.

That these considerations are not far-fetched is shown by the failures of such dams as those at Austin, Tex.; Lock 26, Ohio River, and Austin, Pa. In the first two, at least, sliding took place within, and not on, the foundation rock.

The speaker has not found in the paper any specific description of the foundation material, but the author characterizes it as "bed-rock worn clean by glacial action", and this statement in itself leads one to believe that the foundation conditions are fortunate, and that probably no harmful laminations exist.

Finally, the speaker believes it would be interesting to others, as well as to himself, if the author were to share with his fellow engineers, somewhat more specifically and in more detail, his views as to the effect of the time interval (elapsing between the occurrence of maximum and minimum temperatures) as regards lessening the formation of temperature cracks.

Mr. Wegmann.

EDWARD WEGMANN,* M. AM. SOC. C. E.—Although the multiple-arch dam has only lately come into prominence, this type was adopted for the Meer Alum Dam, in India, more than a century ago. This dam,

* New York City.

Mr. Wegmann.

which is about ½ mile long, is built in plan on a curve, convex up stream, and consists of twenty-one smaller arches, having spans of from 70 to 147 ft. The dam is 39 ft. high and has vertical faces on both sides, except near its crest, where the down-stream face is stepped up stream, in order to reduce the top width.

The Belubula Dam, in New South Wales, was built about 1898. It is 431 ft. long, and has a maximum height of about 60 ft. The lower part consists of a mass of concrete from 1 to 23 ft. deep. The upper part is of brickwork, and has a height of 36 ft. 9 in. In the central part of this brickwork there are six buttresses, 28 ft. from center to center. Between these buttresses there are five vertical, elliptical arches, inclined down stream at an angle of 60 degrees. The spandrels between the arches are filled with concrete which covers the crown of the arches to a depth of 12 in., and joins the side-walls of the dam, which are of concrete. As far as the speaker knows, these two multiple-arch dams are the only ones of this type which were built until recent years.

In 1897, Henry Goldmark, M. Am. Soc. C. E., proposed to build a multiple-arch dam of concrete at Ogden, Utah.* This dam was to be 369 ft. long and 105 ft. high above the foundation at the center of the valley. According to Mr. Goldmark's plan, the dam was to consist of a number of piers, 16 ft. wide and 32 ft. apart in the clear. Alternate bids obtained for building the dam in the manner described, or, as an ordinary "gravity dam", showed a saving of from 12 to 15% in favor of the former plan. Mr. Goldmark proposed to make the thin vertical arches of the multiple-arch dam water-tight by placing a lining of sheet steel on their up-stream side.

About 1900, the speaker was retained to design a multiple-arch dam, 160 ft. high, which was to be built in Virginia, near Washington, D. C. According to the preliminary estimates, this type was found to be about 15% cheaper than a gravity section. Water-tightness was to be insured by coating the up-stream side of the dam with asphalt. Owing to the practical difficulties which might have been involved in building a multiple-arch dam 160 ft. high—a type which, at that time, had only been used for two low dams—the speaker advised his clients to construct a gravity dam. As the promoters of the project could not secure the required financial means, the dam was not built at that time.

George L. Dillman, M. Am. Soc. C. E., has demonstrated, mathematically, the saving that can be effected by building a dam of the multiple-arch type.† He proposed to give the arches between the piers a parabolic section, so as to avoid all re-entrant angles.

* *Transactions*, Am. Soc. C. E., Vol. XXXVIII, pp. 291, 302 (December, 1897).
† *Transactions*, Am. Soc. C. E., Vol. XLIX, p. 94 (December, 1902).

Mr. Wegmann.

It is only of late years that a number of multiple-arch dams have been built.

In 1908 John S. Eastwood, M. Am. Soc. C. E., of Fresno, Cal., built the Hume Lake Dam, in the Sierra Nevada Mountains, as a multiple-arch dam of concrete. The dam is 677 ft. long and about 60 ft. high, and consists of twelve vertical circular arches which are supported by thirteen buttresses. At each end of the dam, a wall, like a core-wall, is built into the side of the valley. In 1910 and 1911, Mr. Eastwood built a similar dam about 200 ft. down stream from the Bear Valley Dam, in California. It has a length of 350 ft. and a maximum height of 91.5 ft. above the foundation. In this case, bids were obtained for building a rock-fill dam having a reinforced-concrete curtain, and, also, for an arched gravity dam of concrete. The multiple-arch dam proposed by Mr. Eastwood was found to be the cheapest and was adopted.

A few more multiple-arch dams have been built. Two of these—the Gem Lake Dam, 700 ft. long with a maximum height of 112 ft. above the foundation, and the Agnew Lake Dam, 30 ft. high and 280 ft. long, were designed by the author. Mr. Jorgensen, however, has not only given an interesting account of how these dams were constructed, but, also, a very complete analysis of the stresses in multiple-arch dams. The speaker compliments him on his excellent paper which will be of value to all engineers who have to design such dams.

Mr. Douglas.

WALTER J. DOUGLAS,* M. AM. SOC. C. E.—About 7 years ago the speaker's firm designed and built, in the Adirondacks, the Garoga Dam, a multiple-arch structure having a 200-ft. spillway of the gravity type. The concrete arches are 60 ft. high, and their thickness at the top is 2 ft., increasing to 4 ft. at the bottom. There was no difficulty in taking care of the thrust, the foundation being of good slate, strong enough to take the concentrated load transmitted by the buttresses. The economy of the multiple arch was found to be small when its cost was compared with that of the gravity section used for the spillway. The speaker thinks that in most cases where the cost of skilled labor is high and material is cheap, the ordinary gravity type is about as cheap as the multiple arch. The difficulties of constructing thin arches, such as those shown in the paper, often more than offset the saving in material.

The speaker's firm has made a great many designs of dams since the Garoga Dam was built, but has only constructed one other of the multiple-arch type. This was the Peck's Lake Dam, built near the same locality as the Garoga Dam. The height of the arches, above the surface of the ground, varies from 25 to 45 ft. As far as the

* New York City.

speaker knows, this is the only multiple-arch dam which has not been built on a rock foundation. The foundations were of slightly indurated sand and gravel, but not hardpan. The pressure is distributed by reinforced concrete slabs at the toe of the buttresses. As a security against horizontal movements, the arches penetrate about 10 ft. into the ground, where they are loaded uniformly by the reaction of the soil, and, therefore, they are catenary in tension. This part of the arches is heavily reinforced with steel rods, which are well bonded into the buttresses. This arrangement worked out very satisfactorily. Mr. Douglas.

The dams described by the author are very interesting, but, the speaker believes, they are not conservatively designed. All engineers who are interested in the development of reinforced concrete, as applied to structures other than buildings and bridges, know that every once in a while something "gets by." Tanks have been built in recent years, which are 4 in. thick at the top, 8 in. at the bottom, and more than 100 ft. high, but the speaker thinks that is no justification for building similar ones. He believes that both the arches and the buttresses of the dams shown in the paper are unnecessarily thin.

The speaker cannot see how the triangular girder, mentioned on page 866, will take up the unbalanced thrust of the arches if one of them should fail, and would ask for more detailed information on this point.

The most serious objection which can be raised against multiple-arch dams is the fact that failure of one unit will destroy the stability of the whole structure. The speaker believes that an occasional abutment buttress, similar in purpose to the abutment piers of arch bridges, consisting of a series of spans should be introduced in the design of multiple-arch dams having a large number of arches.

On page 865, the author says:

"The total vertical load on the section shown in Fig. 6 is seen to be 6 332 tons, and the horizontal water pressure, 5 062 tons, both on a 40-ft. span. If the coefficient of friction is taken at 0.75, it is seen that the actual shear along the base amounts to only $5\,062 - 6\,332 \times 0.75 = 313$ tons. There is considerable steel in the section to help take up this shear, and, therefore, it was not deemed necessary to eliminate the shear entirely."

This statement, the speaker believes, is incorrect. The shearing resistance of an elastic solid is an elastic attribute of the material. The deformation caused by shearing forces, if within proper limits, will disappear after the actuating forces have been discontinued. The frictional resistance is of an entirely different nature, and can act only after the section has failed under shear. The resisting friction can be developed only by minute, but measurable, movements of adjacent planes. This movement is progressive, that is, the dislocation caused by the forces resisted by friction will not disappear when the

Mr. Douglas.

structure is relieved of load, and a second application will necessitate a further movement. In designing one should rely on shear or on friction, and not on both.

As regards the determination of the direct stresses, the speaker would state that the stress computed by the author on page 866, acting on planes at right angles to the resultant, is not necessarily the maximum compressive stress, and that methods are now available for computing the principal stresses in a buttress quite accurately.*

The speaker has made the foregoing criticism because, as the author correctly states on page 851, "the stresses and dimensions can be calculated with great accuracy", in multiple-arch dams, although such calculations are almost impossible in earth or rock-fill dams. The determination of the stresses is subject to many uncertainties, even in gravity dams. The design of this latter type, however, is being developed along scientific lines with very satisfactory progress, and the gravity dam has the advantage of a great number of precedents over the multiple-arch dam.

In the case of solid impervious rock foundation, the speaker decidedly prefers the gravity dam, and doubts whether material saving, if any, can be obtained by the use of the multiple arch, even if this latter would have a considerably smaller volume. The unit price of masonry for the multiple-arch dam is out of all proportion to that of the gravity dam, as illustrated by the price of $22 per cu. yd., given by the author.

If the foundation is fissured rock or other good but pervious material, the multiple-arch dam, generally, should be the more economical type, because the volume of the gravity dam must be increased, in order to meet the uplifting action of the water.

Mr. Duryea.

EDWIN DURYEA,† M. AM. SOC. C. E.—The speaker's home and most of his professional practice are in California, and he is familiar with the general climatic and hydrographic conditions throughout the State and in the Sierra Nevada Mountains, though not with those of Mono County, in which are built the two dams forming the subject of this paper. However, hydrographic conditions are known to be quite uniform throughout the high Sierras of California, and presumably in Mono County they do not differ materially from those of the parts with which the speaker is familiar.

A previous speaker has expressed doubts as to the adequacy of the spillway arrangements of these two dams to pass safely such intense floods as might be expected to occur at long intervals from such a small drainage area as 22½ sq. miles. In most parts of the United States, such apprehensions would be justified, but not in the high Sierras of California.

* See the papers of Levy, Unwin, Hill, Ottley, and Brightmore.
† San Francisco, Cal.

Mr. Duryea.

Throughout that State practically all the year's precipitation occurs during the winter, from about October to about March, inclusive, with hardly any (and none such as will cause floods) during the warmer months of April to September. Hence, in the high Sierras, the year's precipitation is practically all in the form of snow, which accumulates throughout the winter to depths of even 20 ft., or more, settles and packs until melted gradually by the increasing temperatures of the spring and summer, and passes off as stream flow in the form of slowly rising floods, which usually begin in April, culminate in June, and terminate about the middle of July. It is this condition of winter rains in the valleys, which soak the ground and start the growth of the crops, in conjunction with the snow stored in the high Sierras, which by its gradual melting furnishes water for irrigation throughout the growing season of April to September, that causes the very great success of irrigated agriculture in the Great Valley of California.

On the drainage area above these two dams (at elevations of from 9 000 to 12 000 ft. above sea level), and even at much lower elevations, this condition of stream flow from the slow melting of the snow must be marked and invariable; and on that area there can be no direct connection between excessive storm intensities and excessive flood intensities.

The speaker has examined many dams in the high Sierras of California and, at first, was strongly impressed by the apparently very inadequate provisions for spillway capacity and "free-board" of those dams, as judged by necessities elsewhere. Soon, however, he realized that provisions which would have been very inadequate and unsafe in most other regions are quite safe in the high Sierras.

A previous speaker has mentioned the small number of arch dams as yet built in the world, placing the number at only about 15. The speaker has built an arch dam which may not be included in that number. It is the Goodwin Dam, on the Stanislaus River, not far from Stockton, Cal., and serves to raise and divert the waters of that river for the irrigation of the South San Joaquin and Oakdale Irrigation Districts, which together comprise about 144 000 acres. The dam consists of two arches with a buttress between them; there is also a small buttress at the south end of the dam to replace a rock abutment which was badly shattered by the blasting of a canal. The south arch is 299.4 ft. in crest length, with a maximum height of 78 ft.; the north arch is 159.8 ft. in crest length, with a maximum height of 42 ft. The buttress between them is on a ridge of rock (slate) near the middle of the river, and has a maximum height of masonry of only 22 ft.

The two arches have radii (of their vertical up-stream sides) of 135 ft., and are proportioned for "pure arch action" by the ordinary arch formula and for maximum arch stresses of 300 lb. per sq. in. (43 200 lb., or 21.6 tons per sq. ft.). Except that the minimum arch

Mr. Duryea.

thickness (in the upper parts of the arches) was fixed arbitrarily at 8 ft., the arches were thickened 4 ft. arbitrarily at the rock surface (this thickening decreasing to zero 8 ft. above), as a safeguard against possible erosion by the very turbulent waters of the pool just below the dam. The crest was made of a somewhat unusual shape to permit larger flows over it without reducing its strength, and the arches were reinforced against temperature stresses by steel bars, near their crests and for 6 ft. below, near their up-stream and down-stream sides. The thickness of the south arch, 59.8 ft. below its crest (just above the thickened base), is 12.2 ft.; that of the north arch, at the corresponding point, 24.5 ft. below its crest, is 8.0 ft.

The arches are proportioned (aside from the exceptions noted) for 300 lb. per sq. in. and for the maximum arch thrusts caused by floods up to 25 ft. in depth over the crest, making allowance, however, for the relief of the arch pressure by the variable "back-water" against the down-stream sides of the arches. Two measured floods are known (in 1907 and 1911) which would have caused depths on the crest of the dam (had it then been built) of about 15 ft. The dam was completed in 1912, and since then several floods of about 6 ft. in depth have passed over it. The drainage area above the Goodwin Dam comprises about 928 sq. miles of mixed low and high Sierras, from an elevation of 350 ft. above sea level (the crest of the dam) to an extreme height of more than 10 000 ft.

The first requirement in any dam should be certain safety, but the next should be economy; and the usual reason for designing an "arch" dam is that thus considerable saving below the cost of a "gravity" dam often may be effected, without (at least in the judgment of the designer) any sacrifice in safety. The Goodwin Dam is a good example of such a saving in cost. Six other dam sites were surveyed, three up stream and three down stream from the Goodwin site. Estimates of cost were made for "gravity" dams on all seven sites, and for three other plans of arch dams on the Goodwin site. By the choice of the Goodwin site and the two-span arch dam adopted and built, the saving effected was more than half that of the most obvious procedure—the raising of an existing gravity dam 1¾ miles up stream, already the property of the two Irrigation Districts, the enlarging of the intervening 1¾ miles of their existing canal on the north side of the river, and the building of the same length of new canal on the south side.

In 1903, the speaker designed two other arch dams for California streams, neither of which, however, has been built.* The larger one was to have been 138 ft. in maximum height, and made up of eight semicircular arches, supported on intervening buttresses 50 ft. from center to center. The backs or up-stream sides of the arches were to

* *Transactions*, Am. Soc. C. E., Vol. LIII (December, 1904), pp. 172-175.

Mr. Duryea.

have been vertical, with radii of 26.5 ft. The smaller dam was to have been 30 ft. in maximum height, with eight spans of 19½ ft. from center to center of buttresses. The "deck" or up-stream side of the dam was to have been a plane with an inclination of 0.64 vertical to 1.00 horizontal, in order to distribute the foundation pressures more evenly over a rather weak rock foundation. The crown thickness of the deck was to have been 2 ft., and the radii of the inclined semicircular arches forming the under side of the deck were to have been 8¼ ft.

Mention is made in the paper, and by a previous speaker, of the freedom of multiple-arch dams (or other thin dams) from "uplift" forces. Such forces are quite certain to exist in greater or less degree under all thick masonry dams. The speaker recently had an opportunity to measure the uplift forces existing under parts of the base of a high masonry dam (the La Boquilla Dam, in the State of Chihuahua, Mexico, of 244 ft. maximum height). The measurements extended over a period of 22 months, and for depths of water behind the dam (above the foundation level) of from 140.3 to 213.6 ft.; and comprised measurements in thirty-nine holes, aggregating sixty-three or more hole measurements of the uplift. He hopes soon to present these measurements in full to the Society; and will only say now that, although the foundation of that dam, in its natural condition, was a very good limestone, with but few and minor defects (which were all repaired with great care and cost by cement pressure grouting), still the measurements of the pressures show the existence of "uplifts" which, in general, lie on straight lines decreasing from (at the "heel" of the dam) one-third of the depth of water in the reservoir above the foundation plane, to zero at the "toe" of the dam. Incidentally, the dam had been designed to withstand uplifts varying from two-thirds of the depth of the water at the heel to zero at the toe.

Regarding the use and safety of arch dams, one general thought is worthy of serious consideration: Several (only a small proportion, however) "gravity" masonry dams have failed. It is true that these failures were probably always from faults perceived afterward to be due to recognized poor design or construction, and that they would not have occurred had the design and the construction of the profiles and the foundations been in accordance with recognized good practice.

On the other hand (even though most arch dams are much thinner than gravity dams, and though there should be no reason to suppose their profiles and foundations to have been in general designed and constructed more carefully), the speaker does not recall, among the few arch dams as yet constructed, even a single failure.

It is realized that such reasoning is not conclusive, but, nevertheless, it appears to the speaker at least probable that the "arch" dam possesses greater reserves of strength and safety than the "gravity" dam.

Mr. Nishkian.

L. H. NISHKIAN,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has rendered to the Engineering Profession a much needed service by opening up for discussion the subject of multiple-arch dams.

There is no question that, in the future, dams of this type will prevail over other types in many locations, and, therefore, a detailed discussion of methods of design and construction is timely and profitable.

At first glance the structural design of a multiple-arch dam seems to be quite simple, requiring the design of a concrete arch under definite forces, of a buttress to uphold the arch, and of a foundation to hold the buttress in place.

On closer study, many problems arise. The upper and lower ends of the arch barrel are difficult of even roughly approximate analysis, and the designer has to depend largely on his judgment. The weight of the arch between the buttresses is carried partly on the latter and partly on the lower end of the arch. In designing the arch, the author has considered its weight component normal to the buttresses as being carried by arch action to the buttresses, and, presumably, the component parallel to the buttresses as being carried by direct column action down to the footings at the lower end of the arch barrel. In the design of the buttress and foundation, however, it has been assumed that the entire weight of the arch is acting, through its center of gravity, on the buttress.

The writer agrees with Mr. Jorgensen in regard to the method of designing the arch ring, but cannot agree with him in throwing the entire weight of the arch on the buttresses. It appears to the writer that only the weight component normal to the buttress should be considered as acting on it. These two assumptions are widely at variance, and result in a large difference, both in the point of application and in the line of action of the resultant force on the buttress.

The author finds an upper and a lower limit for the direct compression stresses in the buttress. It will be found, however, that the stress produced by the normal component of the arch thrust on the buttress is equal to, or greater than, the maximum stress given in the paper. In this case, the arch thrust, due to water pressure at a depth of 80 ft., is approximately $80 \times 62.5 \times 23.08 = 115\,000$ lb., and the thrust, due to dead weight of arch ring, is approximately $150 \times 3.7 \times \cos. 50° \times 23.1 = 8\,000$ lb., or a total arch thrust of 123 000 lb. This will result in a force of $123\,000 \times 2 \times \sin. \frac{119° 57'}{2} = 213\,000$ lb. per lin. ft. on the buttress. The buttress is here 4.25 ft. thick; therefore, we have a stress of $\frac{213\,000}{4.25 \times 12 \times 12} = 348$

* San Francisco, Cal.

lb. per sq. in. Although in no sense dangerous, this is in excess of the stress of 317 lb. per sq. in., given by the author as the maximum existing in the buttress. One must be careful in using average values of stresses where the average is for a large area. Mr. Nishkian.

The author has made the section of the arch normal to the up-stream edge of the buttress, circular. As is pointed out in the paper, the pressures are not uniform on the arch ring, with the result that, near the top, it is necessary to move the arch out 5 in. at certain points, in order to make its center line coincide with the line of pressure. To avoid this difficulty and maintain a constant shape from top to bottom, it is only necessary to make a horizontal section of the arch circular in shape. A normal section will now be an ellipse, and it will be found that the center line of the arch ring and the line of pressure will coincide very closely for all depths.

It will be necessary to use a three or five-centered curve for the form ribs, and this will entail an extra expense, as the circular form ribs will have to be made in sections also. Furthermore, with a horizontal section circular, the up-stream and down-stream edges will be concentric, with a uniform radial thickness of arch ring. This will result in the normal section of the arch ring being much thicker at the buttresses than at the center, giving it greater stability.

The author has provided a light but very effective method of stiffening the buttress walls, and it is worthy of more general use.

Mr. Williams.

GARDNER S. WILLIAMS,* M. AM. SOC. C. E. (by letter).—No discussion of the multiple-arch dam would be complete without mention of the famous Meer Alum Dam,† near Hyderabad, India, built about 1800, which is made up of a series of full-centered vertical brick arches with radii varying from 70 to 147 ft. These arches are arranged in the arc of a circle, having a crest length of about ½ mile and a height of about 40 ft. This structure appears to be the dean of multiple-arch dams.

On September 1st, 1902, the writer tabulated the bids received by the Ithaca Water Works Company, and a few days later awarded the contract for the construction of the so-called Six-Mile Creek Dam, near Ithaca, N. Y. This dam embodied in its design a section of the inclined multiple-arch type, and is believed to be the first structure of the kind for which a contract was ever let.‡

Prior to the design of this dam, which was made by the writer in the early part of 1902, plans and specifications for an inclined multiple-

* Ann Arbor, Mich.

† *Transactions*, International Engineering Congress, 1915, Waterways and Irrigation, p. 719.

‡ The Six-Mile Creek Dam was discussed in *Transactions*, Am. Soc. C. E., Vol. LIII, and the multiple-arch section is particularly described on page 195 thereof.

Mr. Williams.

arch dam were prepared by Henry Goldmark, M. Am. Soc. C. E., for the Pioneer Power Company, of Ogden, Utah,* the suggestion of this design being due, the writer is informed, to George H. Pegram, President, Am. Soc. C. E. The inclination of the arches was about 25° from the vertical. Subsequently to the work of Mr. Goldmark and prior to 1902, the multiple-arch dam was investigated by James H. Fuertes, M. Am. Soc. C. E., and by the late Emil Kuichling, M. Am. Soc. C. E., independently, but neither of their designs came to the constructive stage.

Since the construction of the Six-Mile Creek Dam, dams of the multiple-arch type have been designed and built under the supervision of the writer in Michigan, Minnesota, and Iowa.

The principles of design laid down by the author differ somewhat from those followed by the writer, and appear to transgress the rules of economical design, since the structure, as described by the author, does not follow the equilibrium curve. As is well known, the curve of equilibrium for an arch under uniform normal pressure is a circle, and, therefore, since the inclined arch may be conceived as made up of an infinite number of infinitesimally thick horizontal arches, the horizontal section of the arch should be a circle and not an ellipse, as seems to have been contemplated by the author. A section of the arch normal to the axis will then be elliptical, and the inclination should be chosen so that this ellipse approaches most closely to the hydrostatic arch for the condition of most constant load. When designed in accordance with these principles, the arch is subjected to the minimum of bending stress, and requires the least material. An increasing thickness of the arch section to the bottom of the dam is hardly necessary, as over the lower one-third, in ordinary cases, the beam action is such as to relieve to a considerable degree the arch action, so that the shell may very properly be made of uniform or even diminishing thickness from the point of one-third the height down.

None of the dams built by the writer has been on a rock foundation, and although it is necessary to be assured of the carrying capacity of the material under the buttresses, this does not preclude the use of such structures on sand, gravel, or clay.

Mr. Howson.

GEORGE W. HOWSON,† ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Jorgensen has presented a very excellent paper on the design and construction of multiple-arch dams. The method of working out the design shows much careful study, and appears to be the last word in the design of dams of this type.

There are several phases of the paper, however, which hardly seem to be in accord with the writer's experience, and there is a general

* *Transactions*, Am. Soc. C. E., Vol. XXXVIII, pp. 290 to 297.

† San Francisco, Cal.

tendency to compare the multiple-arch with the rock-fill dam. These are two entirely different types, each having its own advantages. Mr. Howson

In general, it may be stated that a rock-fill dam may be built on any foundation suitable for a multiple-arch structure; but the reverse is not true. As an example, a rock-fill dam is best adapted to a site where the underlying bed-rock across the floor of the canyon is covered by, say, from 20 to 30 ft. of over-burden. Here it may be necessary to carry only the thin cut-off wall down through the overlying material into solid rock; and the great bulk of the dam, the loose drop fill, may be built on the over-burden. It must be known, of course, that the foundation under the rock fill is suitable, though it may not be a foundation on which the buttresses of a multiple-arch dam should be built. Mr. Flinn has brought out this point in comparison with a solid masonry dam, but his comparison of economy relative to the foundation is even more applicable in the case of a rock-fill structure.

It is then seen that the problem of choice between rock-fill and multiple-arch types presents itself only at a site where a good foundation for the buttresses is exposed, or is found within a limited depth of excavation. Here the final economic balance may be in favor of either type, depending on the particular cross-section of the canyon, the transportation problem, and the general topography of the site. The writer, however, believes that, in a majority of cases where it is possible to consider a choice of types, the relative cost of a multiple-arch dam and a rock-fill dam will be in favor of the former.

Mr. Jorgensen is correct when he states that the water-tightness of a dam depends to a much larger extent on the quality of the concrete in the arches than on the thickness of the latter. The Strawberry Rock Fill Dam, built recently by the Sierra and San Francisco Power Company, may be said to be bottle-tight, although it depends on a reinforced concrete apron only 18 in. thick, under a 130-ft. head, which thickness tapers to 9 in. at the crest. A multiple-arch dam should be built only under the most competent engineering supervision. A few failures of dams of this class due to poor construction would condemn all such structures, in the public opinion.

L. R. JORGENSEN,* M. AM. SOC. C. E. (by letter).—Throughout the discussion there has been a tendency to compare the cost of multiple-arch dams with that of gravity dams. As a general rule, it can be said that the multiple-arch dam is the cheaper, the more expensive the building material. For dams of moderate height, it is probably always cheaper, but not for heights of more than 130 ft. The only sure way of finding out is to estimate the cost of each type for any given location. Mr. Jorgensen.

The system of struts has not been designed to help to prevent settlement or sliding of the buttresses; it cannot do that, and it is not

*San Francisco, Cal.

Mr. Jorgensen.

necessary, for, in these particular cases, the rock foundation is possibly twice as strong in shear and crushing as the concrete in the buttresses. The struts are to stiffen the buttresses, and to transmit any unequal arch thrust which normally might exist at any place, due, for instance, to the adjacent arches being built, during periods of different temperatures, into the side-hill where the struts are anchored. The two struts close to the arch (Fig. 4) will also transmit to the side-hill the abnormal unbalanced thrust which might occur should one arch accidentally fail, thereby preventing a complete collapse of the dam. Should the struts fail at the same time as the corresponding arch—which is probable—the unbalanced thrust would have to be taken up in tension by the steel in the line of struts on each side of the break. The eight 1-in. square rods should be able to hold 400 000 lb., as there are no laps between the knee-braces belonging to the different buttresses. The triangular girder mentioned on page 867, simply stiffens the up-stream ends of the buttresses so that they will stand up between points of application of the struts. The struts then transmit the unbalanced thrust to the side-hill, either by tension or compression, or by both.

Mr. Blackwell's criticism as to spillway capacity has been answered by Mr. Duryea. There occurs no precipitation of such quantity as to cause flood when the reservoir is full. During the season of maximum ice pressure—that is, in late winter or early spring—Gem Lake Reservoir will be nearly empty. Agnew Lake Reservoir is to be used as a forebay, and the daily fluctuations will break up the ice; therefore, it has not been deemed necessary to design these dams for ice pressure.

In comparing the three forms of multiple-arch dams mentioned by Mr. Flinn, the writer regards the one with the sloping up-stream face as the best and only one to consider. In this construction, the water pressure acting on the sloping face is the largest single factor contributing to stability, and this factor would be absent in a dam having a vertical face.

As to the leakage of different types of dams, this will depend much more on the care with which they are constructed than on their type and design.

The writer agrees with Mr. Scheidenhelm, that, after all, in the case of multiple-arch dams, one must, for perfect safety, insist on an unyielding foundation.

As an example of the influence of the time factor, let it be assumed that an arch is subjected suddenly, or during an interval of a few hours, to a temperature drop, penetrating through the arch material, of, say, 80°, sufficient to cause a maximum tension in the concrete of, say, 300 lb. per sq. in. If this same temperature drop of 80° was brought about during an interval of 20 or more days, the

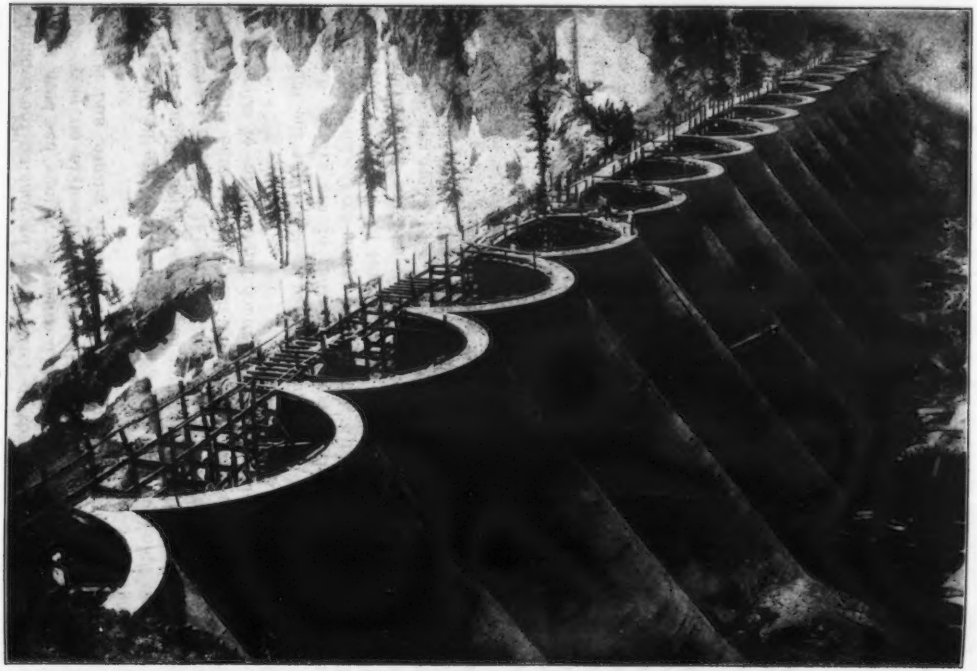

FIG. 22.—GEM LAKE DAM.

tension in the concrete would only amount to about 100 lb. per sq. in., and, naturally, the tendency to form cracks would be much less than in the first case. Daily temperature changes will hardly penetrate the arch sufficiently to have any practical effect, but seasonal temperature changes will, and here is where the action of the time factor tends to lessen the tendency to form cracks by making the concrete stretch more for the same stress, because the change has been slow. The publication by Mr. F. R. McMillan, referred to on page 859, gives detailed results of numerous tests of this nature, and is very interesting. Mr. Jorgensen.

The multiple-arch dam at Ogden, Utah, referred to by Mr. Wegmann and Mr. Williams, is of unusually conservative design, and it is no wonder that the bid price was only from 12 to 15% lower than the bid price on an ordinary gravity dam for the same site, as Mr. Goldmark's design surely has a very much larger factor of safety than the ordinary gravity dam.

Mr. Douglas says, "The unit price of masonry for the multiple-arch dam is out of all proportion to that of the gravity dam, as illustrated by the price of $22 per cu. yd. given by the author." This high price, however, is due to the high cost of the material at this particular place (Gem and Agnew Lakes), and not to the type. A multiple-arch dam in an accessible location, and where conditions are ordinarily favorable, can be constructed for $13 per cu. yd., and this price may possibly include the steel reinforcement.

Mr. Douglas is correct in stating that frictional resistance can only act after the section has failed under shear. One should rely on shear or friction. The maximum unit shear of approximately 106 lb. per sq. in. existing at Elevation 80 below the crest can hardly be considered excessive. In this case the area of the arch ring has been added to the area of the buttress proper, as both must act to resist shear at the same time. The fact that there is a very large vertical load should be of some comfort, as it improves the ability of the buttresses to withstand actual shear.

The stress on the buttresses is given between two limits on pages 865 and 866. The following formula (which can be found in some handbooks) gives the maximum stress on any horizontal plane more definitely:

$$\text{Ideal maximum stress} = \frac{m-1}{2m} \times \text{unit vertical compression} + \frac{m+1}{2m} \sqrt{(\text{unit vertical compression})^2 + 4\,(\text{unit horizontal shear})^2}$$

(m = Poisson's ratio = 5 for concrete). Then, at Elevation 80,

$$\text{Ideal maximum stress} = 0.4 \times 192 + 0.6\ \sqrt{192^2 + 4 \times 106^2}$$
$$= 76.8 + 171.6 = 248.4 \text{ lb. per sq. in.}$$

Mr. Jorgensen.

It is true, as pointed out by Mr. Nishkian, that the stress produced by the normal component of the arch thrust on the buttress is greater than the stress (317 lb.) produced by the resultant. This, however, is the case only toward lower elevations, where the "column" is very short; the normal component of the arch thrust diminishes rapidly toward higher elevations. The ideal maximum stress of 248.4 lb. per sq. in. diminishes less toward the upper system of struts; and, although the column ratio is about 20, there might be, and very likely is, some column action due to the ideal maximum stress.

Both Mr. Nishkian and Mr. Williams point to the elliptical arch as being the most correct form. Thus far, the writer has contended that the additional work of making a three-centered arch would outweigh any possible gains; however, he will soon see how the elliptical arch works out on a multiple-arch dam structure with the construction of which he is connected.

The writer cannot agree with Mr. Williams that the arch can be of uniform, or diminishing, thickness downward from the point of one-third the height of dam. Even though the stresses may not be excessive, the penetrating power of water increases with the depth, and, therefore, the thickness of the wall should increase logically. It must be kept in mind that even a sweat on the down-stream face will produce icicles in cold weather, and it is not yet known to what extent, if any, this will damage good concrete. It is known that it damages poor concrete. Good concrete is fairly water-tight, and gunnite is remarkably so, but, nevertheless, it requires great care to construct a water-tight structure. Some of the arches on the Gem Lake Dam are absolutely tight, some of them sweat in places, and a few drip in places. A few small springs have formed behind the dam, and a trickle of water comes under one arch; but, all told, the total leakage is very small.

Some tests were carried out in the Laboratory of the University of California on the water-tightness of plaster "shot" on the dam face with a cement gun. Several plaster slabs, from $\frac{5}{8}$ to $1\frac{1}{2}$ in. thick, made at Gem Lake, were tested with water pressures ranging from 700 to 1 600 ft., for several hours, with no moisture coming through the slab. One 1-in. slab held a head of 1 610 ft. for $2\frac{1}{2}$ hours without showing moisture, then the water pressure was raised gradually to 3 400 ft., and the specimen broke in bending, having leaked a little just before breaking.

Mr. Howson states the case correctly when he says that a rock-fill dam is best adapted to a site where the underlying bed-rock across the floor of the canyon is covered by, say, from 20 to 30 ft. of over-burden, as it is only necessary to carry a thin cut-off wall down through the overlying material.

The author thanks those participating in the discussion for the interest shown.

Paper No. 1397

THE RECONSTRUCTION OF THE STONY RIVER DAM*

By F. W. Scheidenhelm, M. Am. Soc. C. E.

With Discussion by Messrs. J. W. Ledoux, J. K. Finch, P. P. Rutenberg, Fred F. Moore, W. S. Downs, H. L. Coburn, H. F. Dunham, Orrin L. Brodie, William Cain, Charles E. Gregory, Kenneth C. Grant, L. R. Jorgensen, Edward Wegmann, Irving P. Church, M. M. O'Shaughnessy, Joel D. Justin, Ross M. Riegel, and F. W. Scheidenhelm.

Synopsis.

This paper describes the reconstruction and strengthening of the Stony River Dam, which failed on January 15th, 1914. After the failure, on investigation of the foundation conditions and the parts of the structure which remained intact, it was found that those portions required strengthening and revision in a number of important features. The lessons indicated by the results of the investigation are significant. The dam, even as reconstructed and strengthened, is founded largely on clayey soil, thus presenting most difficult foundation conditions. It is about 50 ft. high above stream level and 85 ft. between the lowest part of the cut-off wall and the top of the parapet.

A brief résumé of the previous history of the dam, including the causes of its failure, is first given, together with a statement of the controlling geological and foundation conditions. Then follows an exposition of the treatment of the more important problems involved in the reconstruction.

* Presented at the meeting of March 21st, 1917.

The spillway capacity was increased approximately to 1 840 cu. ft. per sec. per sq. mile. The reasons for providing such unusually large capacity are given, and also a method of determining the absorption effect of a reservoir in smoothing off the peak of a flood.

The most important problem to be solved was that of giving the original structure a sufficient margin of safety against sliding. The results of tests of frictional resistance and shearing value of various soils, principally clays, are stated, and also the various schemes considered for increasing the resistance to sliding. The method adopted is believed to be new, and consists in the use of anchoring walls extending to a considerable depth into the underlying foundation soil, and, in effect, utilizing the weight of that underlying soil as well as the resistance (to horizontal movement) of the soil immediately down stream from the structure. The details of construction are unique. The same principles were applied, with important differences in detail, at the new spillway which replaced that portion of the structure which had failed or was wrecked.

Brief reference is made to the resistance of the structure—both in its original state and as strengthened—to failure by overturning.

The bearing value of clayey soil is discussed, and the results of tests made at the site are given. The anchoring wall added at the toe of the original structure was utilized to decrease the pressures of the foundation soil. The method of strengthening the original footings is described. Pressure grouting was used to remedy other faulty footing conditions.

The means of cutting off percolation and leakage through the foundation soil are described, also the provision made for drainage, both of clayey soil and of shale rock, together with the controlling considerations in these and similar cases.

The higher bulkhead portions of the original structure were housed in by curtain-walls and roofs in order to prevent serious freezing in the drainage system and to fulfill certain other functions as described.

Miscellaneous problems in the reconstruction and strengthening involved the type of structure for the new spillway, the strength of the original decks and buttresses, the underpinning of the portions of the original structure immediately adjoining the new spillway, the construction of a protecting and anchoring toe-wall at the old spillway, the

special method of constructing an anchoring wall at the heel at the outlet-gate sections, and the provision of an outlet channel.

The reliable storage capacity of the reservoir was increased by 25 per cent. This increase was made permissible by the use of special steel bars or pins acting as flash-board supports. These pins were developed for the purpose, and automatically and reliably allow the flash-boards to be swept off the spillway crests when the head-water reaches a pre-determined level.

The materials, methods, and cost of reconstruction are discussed briefly. Approximately, as much concrete was required for the reconstruction as had been placed in the original structure.

The Stony River Dam and Reservoir have again been in service since May, 1915, and the observed results of the reconstruction and strengthening are stated in connection with the corresponding features of design.

Reconstruction of Stony River Dam.

The failure and reconstruction of the Stony River Dam are of interest, not because of the height or dimensions of the structure, but because it is largely through failures and mistakes that engineers must learn the limitations of previous methods of design and construction and gather hints as to new methods to be used. Furthermore, in the case of this structure, the extremely difficult foundation conditions made the problem of providing a safe dam at that site one requiring more than usual thought and care. Finally, much interest attaches to the methods used to make safe the existing structure, that is, that portion which remained intact after the failure—it being noted that a comparatively small section of the dam actually failed.

It seems proper at this point to emphasize the fact that, until a structure has actually failed, its "safety" is relative. Seldom do any two engineers have exactly the same conception or measure as to the factor or margin of safety possessed by a given structure. Especially is this true in the case of dams.

As a preface to the description of the reconstruction and the problems involved therein, the following brief review of the previous history of the dam is pertinent. The details have been gathered from various sources, and are based on the best information available to the writer.

Previous History.

In 1911 the West Virginia Pulp and Paper Company, owner of the dam, determined to investigate the feasibility of constructing on the head-waters of the North Branch of the Potomac River a storage reservoir by which to increase the flow of the river at its Piedmont pulp and paper mill at Luke, Md., near Piedmont, W. Va. Its requirements of water for manufacturing purposes were such that during low-water seasons the normal flow of the stream was at times inadequate.

After an investigation of the available sites on the drainage area above the Piedmont mill, the owner chose the water-shed of Stony River as offering the best conditions for the construction of a storage reservoir. Stony River—which at the site of the dam drains only 11.4 sq. miles, and is therefore only a creek—lies entirely within Grant County, West Virginia, flowing into the North Branch of the Potomac River from the south a short distance above Schell, W. Va. The mouth of Stony River is approximately 26 miles up stream from the Piedmont mill. It is only near its upper end that the profile is flat enough to allow the construction of a reservoir at a practicable cost per unit of water stored.

Two sites examined in the upper reaches of Stony River were abandoned, because of interference with a seam of commercial coal in one case and the presence of quicksand in the over-burden in the other. The third and final site was chosen with the approval of Edward Wegmann, M. Am. Soc. C. E., who had been engaged by the owner as Consulting Engineer for the purpose.* This site is approximately 3 350 ft. above sea level.

An examination of the foundation conditions, deemed at the time to be adequate, was made by test pits and auger borings. After this examination it was concluded that the depth to bed-rock was so great as to prohibit the construction of a solid masonry dam, and that the surface soil in the neighborhood of the dam was not of such a nature as to warrant the construction of an earth fill dam. It had been the intention of the Company to build a dam of one of these types, but, under the circumstances, it was decided to construct a hollow reinforced concrete structure with a height of about 50 ft. above the original water surface and a length of about 1 075 ft. The resulting capacity

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 1069.

was approximately 1 533 000 000 gal. below the elevation of the spillway crest.

Certain companies were invited to submit plans and bids for the construction of such a dam. On the basis of the bids received,* a contract was entered into with Mr. Frederick G. Webber, President of the Webber Construction Company, for the construction of a dam according to plans submitted by the Ambursen Hydraulic Construction Company, licensor.

Work was begun by the contractor about June 1st, 1912, and carried on until February, 1913. At that time the Company took the work from the original contractor and engaged the Ambursen Hydraulic Construction Company to complete it. The latter company took over the work in March, 1913, and completed it in July, 1913.

The details of the original construction have been fully described by G. H. Bayles, M. Am. Soc. C. E., Resident Engineer for the owner during the construction.† Variations of actual conditions from those assumed in the original design and construction will be discussed later in this paper. Fig. 1 shows the dam as originally built.

The storage of water in the reservoir was begun in May, 1913, that is, prior to the completion of the dam. The reservoir, however, was not completely filled until the late autumn, and the water level had been at the spillway crest for about 65 days prior to the failure of the dam. There had been but little flow over the spillway.

The failure occurred on January 15th, 1914, the cause, in the opinion of the writer, being the washing out of the foundation soil by leakage from the reservoir under an up-stream cut-off wall of inadequate depth. It is probable that there were conclusive signs of impending trouble for several days earlier (perhaps as early as January 10th), in the way of water flowing through weep-holes in the floor or footing of the dam at or near the section where failure finally occurred. With proper attention on the part of the operating attendant at the dam, the reservoir could probably have been drained in time to avoid the failure which occurred.

It is not the purpose in this paper to discuss the failure in detail, inasmuch as it has been described adequately in articles in engineering periodicals.‡ For the sake, however, of making clear the description

* *Engineering News*, September 5th, 1912.
† *Engineering News*, January 22d, 1914.
‡ *Engineering News*, January 22d, 1914; *Engineering Record*, January 24th, 1914.

of the design, and the work involved in the reconstruction, Figs. 2, 3, and 4 are submitted, showing the portion of the dam which failed.

As a matter of personal interest, the writer visited the site as soon as practicable after the failure, and spent portions of January 18th and 19th, 1914, there. At the time of his inspection the main outlet-gate in the dam had been opened, and the reservoir had already been completely drained, so that Stony River was flowing in its normal channel at the center of the valley, and not through the break, which occurred at a higher level, and on the west bank of the valley. Based on the inspection made at that time, the writer prepared and furnished to the Public Service Commission of West Virginia, at its request, his conclusions as to the failure of the dam. These conclusions, dated January 22d, 1914, were as follows:

1.—Complete failure occurred between Buttresses 11 and 16, involving a length of approximately 75 ft. out of a total crest length of approximately 1 075 ft. At least three additional bays, *viz.*, as far eastward as Buttress 19, were damaged so as to require practically complete rebuilding. Similarly, the faulty cut-off wall construction and certain damage done westwardly from Buttress 11 must be remedied.

2.—Failure was caused by the undermining of the over-burden or soil under the up-stream cut-off wall. The over-burden is in general clayey, but non-homogeneous. Undermining was initiated by leakage of water from the reservoir under approximately 25 ft. head through permeable over-burden not penetrated by the cut-off wall.

3.—The pressure of ice on the reservoir against the deck of the dam did not contribute to the failure.

4.—The dam was of the Ambursen, hollow, reinforced concrete type. The type of dam was not in any way a cause of failure.

5.—The quality of concrete and character of construction were good.

6.—Failure occurred where the up-stream cut-off wall extended only a short depth (5 to 7 ft.) into the over-burden. Where the up-stream cut-off wall extended to a comparatively greater depth (said to be to rock), failure was checked, and the cut-off wall is still intact.

VOL. LXXXI, No. 1397.
SCHEIDENHELM ON
RECONSTRUCTION OF
STONY RIVER DAM.

7.—The preliminary exploration and investigation of the dam site were not sufficiently comprehensive, and did not develop essential and all-important facts.

8.—The technical advisers consulted in connection with the foundation of the dam were not familiar with local conditions. The geological factors at the dam site were not sufficiently considered.

9.—The conditions obtaining at the Stony River dam site are such that a safe dam could be built there. Whether the portion of the dam still intact, and with its core-wall reported to extend down to rock, has sufficient factors of safety, depends on facts of which we do not have accurate knowledge. Further investigation should be made as to this question.

10.—The mechanism for operating the outlet-gates and valves is not sufficiently protected against ice formed by otherwise harmless leakage through the deck of the dam; nor is such mechanism readily accessible under all conditions.

11.—Although the dam should, and could, have been designed and constructed so as to be absolutely safe, regardless of the gate mechanism and the character of the attendance, yet, even in this instance, had the attendant been observant and resourceful, it would have been possible to open the sluice-gates in ample time to drain the reservoir sufficiently to have obviated failure of the dam.

12.—Published newspaper reports have grossly exaggerated the details of the failure and the extent of the damage to property.

In general, the foregoing summarized conclusions on the part of the writer still hold good. It may be well to point out, however, that the writer distinguishes between the "character of construction work" and the design of the structure.

The location of the break in the dam, with reference to the entire profile, is shown on Plate IX. Complete failure, as previously stated, involved a length of about 75 ft., *viz.*, between Buttresses 11 and 16, but certain additional damaged work was removed, so that the gap in the dam to be closed during the reconstruction work comprised a total length of 135 ft., *viz.*, between Buttresses 10 and 19.

In February, 1914, the writer was engaged as Consulting Engineer by the West Virginia Pulp and Paper Company to take charge of the

proposed reconstruction. He desires to emphasize the point that he was not requested to place the responsibility for the failure, nor did he attempt to do so. It is fair to note, however, that in this case, unlike most other failures, no criticism has been heard directed against the owner, that is, against the executive officers of the West Virginia Pulp and Paper Company, on the score that economy was preferred to safety. Moreover, in connection with the proposed reconstruction, the executive officers of the Company proceeded on the principle that either the dam should be reconstructed so as to be reliably safe, or no attempt should be made to utilize the damaged structure. The same attitude was manifested throughout the entire period of reconstruction.

Prior to the final decision to proceed with the actual work of reconstruction, the entire structure and foundation conditions were investigated carefully, in order to discover any features of design or construction involving insufficient margins of safety. Not until about August 1st, 1914, did the owner finally decide to reconstruct. The work was finished in May, 1915, though the storage of water in the reservoir had been resumed several months earlier.

Geological and Foundation Conditions.

The available information regarding foundation conditions was found to be so inadequate that the investigation which followed had to be made practically as complete as though there had been no dam on the site. In fact, the existence of a dam at the site necessitated additional exploration to determine the adequacy of the cut-off.

An F-1 Davis Calyx core-drill was placed on the work, and by it ten holes were sunk. The deepest hole was sunk to approximately 100 ft. below ground surface; several other holes were carried to depths of approximately 80 ft. Usually, the strata penetrated were sufficiently tight to retain in the hole the water necessary for the shot-drilling process. In other cases, however, especially on the east bank of the valley, seams were encountered in the rock, and these were of such capacity that it was difficult to keep sufficient water in the holes to allow the drilling to proceed.

Numerous test pits were sunk, the majority being immediately adjacent to, and up stream from, the original cut-off wall. Such test pits not only exposed the character of the over-burden, but also permitted an examination of the original cut-off and the efficacy of its seal into the bed-rock. Several of the test pits extended to a depth of

approximately 45 ft., and were sunk at considerable expense, because of the inflow of water and the necessity for sheeting the pits for practically their entire depth.

On Plate IX are shown the locations of the core-drill holes, the logs thereof, and the "lay" of the rock strata as deduced from the logs and other records. This plate shows, also, the profile of the original ground surface of the valley. It is apparent that the axes of the original valley and of the present valley do not coincide. By "original" valley is meant that valley which existed at the time the stream was still eroding the bed-rock and was in immediate contact with that rock. At that time the axis of the valley was approximately at the west end of the old spillway, or at about Station 5 + 50. As time went on, the stream ceased its cutting or eroding action and began to build up the floor of the valley by depositing sediment and gravel. At the sides of the valley this process was apparently aided materially by "slips" and talus from the hillsides.

During this process Stony River meandered back and forth across the valley until at present the axis of the valley is approximately at Station 4 + 40. If, in the profile shown on Plate IX, the original and the present locations of the stream-bed were to be connected by a line passing through all the intermediate locations of the stream-bed, such connecting line would have an extremely irregular or zigzag course. Water-worn boulders and gravel were found strewn through various portions of the over-burden as exposed by the exploratory work, testifying to the fact that they had been deposited by the stream in ages past.

The Stony River Valley lies in the geological formations of the Carboniferous period. The lower portion of the valley, at the dam site, lies in what is known locally as the Savage formation, one of the principal features of which is the Davis or Kittanning coal, which is of commercial importance throughout this region.

The general characteristics and slope of the formations are indicated roughly in the Piedmont folio (West Virginia) of the United States Geological Survey. The detailed geological correlations at the dam site, however, were far from simple. Variability, rather than uniformity or persistency, characterizes the Savage formation, and nowhere is this exemplified better than at the site in question. From the core-drilling data it is apparent that lentils abound, that relatively soft

strata are interbedded with hard strata, and, what is of even greater importance, that the geological horizons, which at one location offer impervious strata, show decidedly pervious strata at other locations.

The characteristic rocks are shales of a laminated or seamy character, as shown in the typical section, Fig. 6. Here and there lentils of coal and black slate are interbedded in them. At approximately the location of the break, *viz.*, in the neighborhood of Station 2 + 00, the shales were found to be so crumpled and crushed by folding near the surface as to require their excavation in the process of reconstruction.

It is not believed that this condition had any relation to the failure of the dam, but it is probably true that, once the dam had failed and the reservoir was being emptied through the break, the erosion of the bed-rock immediately down stream from the place of failure was facilitated considerably by this local surface crumpling of the shales.

At the east side of the valley (the left side of the profile in Plate IX) heavy sandstones were encountered. Evidently, at the time the valley was formed by the process of stream erosion, the sandstones caused the formation of overhanging cliffs, under which the softer strata were eroded. Frost and other natural forces, however, had their effect, even on these sandstone cliffs, with the result that they became fissured, though the boulders which were thus cracked off probably did not move far from their original location. In fact, excavations made under the original cut-off showed that in the original construction certain of these boulders or false cliffs had been mistaken for bed-rock, and that under them there was actually pervious material, such as the disintegrated coal shown in the profile immediately to the west of Station 9 + 00.

The over-burden or foundation soil at this site is mainly of a clayey nature. It is far from being homogeneous, as is evident from Fig. 7, which shows typical soil conditions at Buttress 10. In general, the soil near the surface is loamy and more pervious than that immediately overlying the bed-rock. Near the middle of the valley, however, the conditions are reversed, and there deposits of pervious materials, such as gravels, were found at considerable depths.

A catalogue of the constituent materials of the over-burden shows:

Yellow clay.....impervious, of fair bearing value.
Blue clay.....impervious, of fair bearing value.

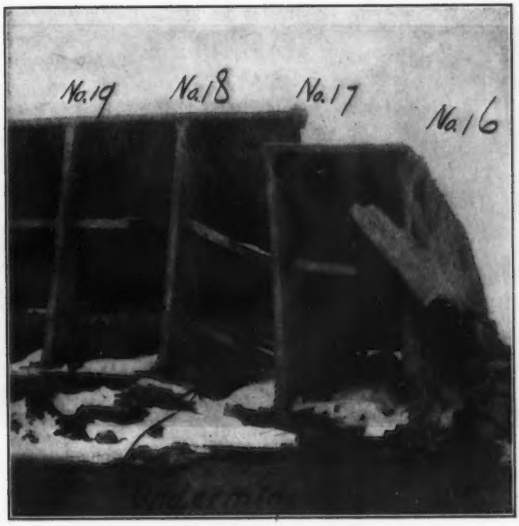

FIG. 5.—BUTTRESSES 16 TO 19, STONY RIVER DAM, MARCH 16TH, 1914.

FIG. 6.—TYPICAL SECTION OF SHALE AT SITE OF STONY RIVER DAM, NEAR POINT OF FAILURE.

FIG. 7.—TYPICAL FOUNDATION SOIL CONDITIONS AT BUTTRESS 10, STONY RIVER DAM.

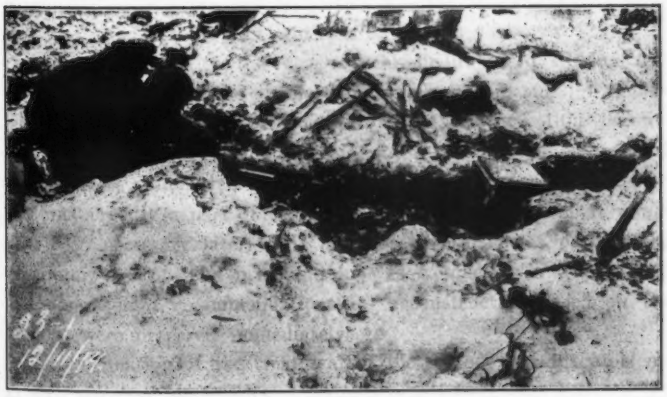

FIG. 8.—TEST OF FRICTIONAL RESISTANCE.

Black clay or gumbo..impervious, of fair bearing value when dry or only moist, but of poor bearing value when saturated with water.
Sand and gravel.....pervious, but of good bearing value.
Loamy sand.....in minor quantities, pervious, of poor bearing value.
Sandy clay.....fairly water-tight, of fair bearing value.
Shale fragments.....not in place, and in various stages of disintegration, mostly permeable, of fair bearing value.
Boulders.....in considerable numbers, and, of course, of excellent bearing value.

The bearing values, as referred to in the foregoing, are relative; comparison is made with the bearing values of other materials present in the over-burden, and not with those of granite or even of the shale rock on which the new buttresses, 11 to 18, inclusive, are founded. The materials occurred in no regular order.

Such foundation conditions required the most serious consideration and care in construction. In general, the designs involved in the work of reconstruction were based on the assumption that the worst conditions might exist at any bay. In view of the findings of the exploration work, it appeared logical, however, to attribute higher bearing values and greater resistance to percolation to the foundation soil of the east hillside, that is, roughly, east of Station 5 + 00, for in that portion of the valley there is more clay, and it is of a better character.

Simultaneously with the work of core-drilling and sinking test pits, the wrecked portions of the dam were removed, and the underlying foundation soil was stripped from the bed-rock, thus permitting a first-hand study of the strata on which were to be founded the buttresses which were to replace those taken out. Such excavation was actually a part of the reconstruction, inasmuch as it would have been necessary later, if it had not been made as part of the exploratory work. The investigation was completed in June, 1914, and designs and recommendations for reconstruction based on the findings were prepared immediately.

An explanation of the treatment of the more important problems of the reconstruction follows.

Spillway Provision.

Original Spillway Capacity.—A problem affecting most of the other features of design—because it determined the probable maximum head-water level, and hence affected the probable maximum stresses—was that of the spillway capacity to be provided. The original spillway provision was apparently inadequate, being only about 2 800 sec-ft. with water level at the elevation of the original crest of the bulkhead sections of the dam, *viz.*, Elevation 139 (Plate IX). In fact, it is likely that the actual safe flood discharging capacity would have been somewhat less, for the original spillway crest had not been given the most advantageous shape.

Assuming the drainage area to be 11.4 sq. miles, as shown by the "Piedmont" topographical quadrangle issued by the U. S. Geological Survey, the original spillway capacity was less than 250 sec-ft. per sq. mile of drainage area.

Pertinent Records of Flood Flow.—In general, in a given region, the smaller the drainage area the larger the maximum unit run-off and flood flow. So-called cloudbursts are limited as to area affected, but certainly the Stony River drainage area is sufficiently small to fall within the territorial limits of a cloudburst. It happens that there are two important and applicable records* of flood discharge, namely, those of the floods on:

Cane Creek, at Bakersville, N. C., May 19th-20th, 1901; drainage area, 22 sq. miles; estimated maximum discharge, 1 386 sec-ft. per sq. mile; elevation above sea level at point of measurement, approximately 2 450 ft. (U. S. G. S. datum); elevation of highest point in water-shed, approximately 5 330 ft.; and

Elkhorn Creek, at Keystone, W. Va., June 22d, 1901; drainage area, 44 sq. miles; estimated maximum discharge, 1 363 sec-ft. per sq. mile; elevation at point of measurement, approximately 1 600 ft.; elevation of highest point in water-shed, approximately 3 365 ft.

The fact that both of these extreme floods occurred in the Southern Appalachian mountain system, in which the Stony River dam is situated, and the further fact that the several drainage areas in ques-

* *Engineering News*, August 7th, 1902.

tion, including that of Stony River (with the dam at approximately Elevation 3 350 and the highest point in the water-shed at approximately Elevation 4 200), are at not widely differing altitudes, cause these two records to be exceptionally valuable for purposes of comparison. These drainage areas are apparently quite similar in their physical characteristics.

The records referred to were reported by Mr. E. W. Myers, then Engineer of the North Carolina Geological Survey, and Assistant Hydrographer of the U. S. Geological Survey. It is to be admitted that the method of measurement was probably not such as to warrant expressing the discharges to the nearest second-foot; on the other hand, an examination of the data does not warrant one in disregarding the records or assuming that the maximum flood discharges were materially less than those stated.

Although the Cane Creek flood was estimated to have been actually of slightly greater intensity than that of Elkhorn Creek, yet relatively, and for the purpose of predicting the maximum probable flood discharge from the drainage area above the Stony River dam, the Elkhorn Creek flood is of considerably greater importance, because of the fact that the drainage area at the point of measurement is twice as great as in the case of Cane Creek. For detailed data, however, one must work from the records of the Cane Creek flood, as in that case, fortunately, Mr. Myers made an estimate of the average discharge during each hour of the flood, as well as an estimate of the maximum discharge during the flood. In the graph of this flood, Fig. 12, the run-off of Cane Creek has been reduced in proportion to the drainage area, so as to be applicable to the drainage area above the Stony River Dam. Granting that the Cane Creek data are only approximate, they nevertheless appear to be well worth while adopting as a basis of study.

It is noteworthy that all available records indicate that, in the region under consideration, maximum rains, of sufficient duration to tax the equalizing capacity of the reservoir, do not occur in the early spring, and hence do not coincide with the melting of the snow. For this reason it was assumed that the greatest flood to be anticipated at the Stony River Dam would be due solely to rainfall.

Comparison with Records of Maximum Rainfall.—For practical purposes, it may be assumed that the Elkhorn and Cane Creek floods

were of equal intensity when reduced to a unit basis. The following remarks, based on the Cane Creek record, are consequently applicable also to the even more important Elkhorn Creek record.

Both these floods were undoubtedly caused by local cloudbursts which occurred after previous rains had saturated the respective drainage areas. For the purpose of comparison with rainfall records, therefore, it may be assumed that the maximum run-off per hour was approximately equal to the maximum rainfall per hour. In the case of the Cane Creek flood it is reported that, during the hour of maximum run-off, the discharge was at an average rate of 1 202 sec-ft. per sq. mile, corresponding to a rainfall at the rate of approximately 1.86 in. per hour.

Referring to Fig. 9, showing the duration of maximum intensities of rainfall in the United States, it will be noted that the maximum rate of rainfall previously derived for the Cane Creek flood falls well within the limits of the highest records shown.

Bulletin D of the U. S. Weather Bureau, the basis of the principal data of Fig. 9, includes only records obtained after the establishment of self-registering gauges in 1893, but prior to 1897. Because of the limited period which it covers, and, further, because of the limited number of precipitation stations involved, it is certain that the data of *Bulletin D* are only indicative, and not comprehensive or conclusive.

This fact is illustrated further by the record of an excessive rainfall at Raleigh, N. C., on Tuesday, July 14th, 1914, which has been plotted on Fig. 9. It should be remembered, of course, that records of excessive rainfall such as that at Raleigh are not of controlling importance in the present case, because they are not of sufficient duration to tax the equalizing capacity of the reservoir.

On Fig. 9 there has also been plotted a curve (*b*), derived from the graph shown on Fig. 12, on the assumptions that during the 90 min. of greatest run-off, in the case of the Cane Creek flood, the rainfall likewise was at its maximum, and that during such period the run-off was equal to the rainfall, variations being simultaneous. These assumptions, of course, are not strictly true, as the maximum rate of run-off could not have been equal to the maximum rate of rainfall. Necessarily, there must be some equalization, and it is evident from an inspection of the Cane Creek flood curve (*b*) of Fig.

9 that in this instance there must have been a considerable difference between the maximum rates of run-off and rainfall.

Yet, even allowing for a reasonable equalization or smoothing off of the peak of the rainfall, as compared with the peak of the run-off,

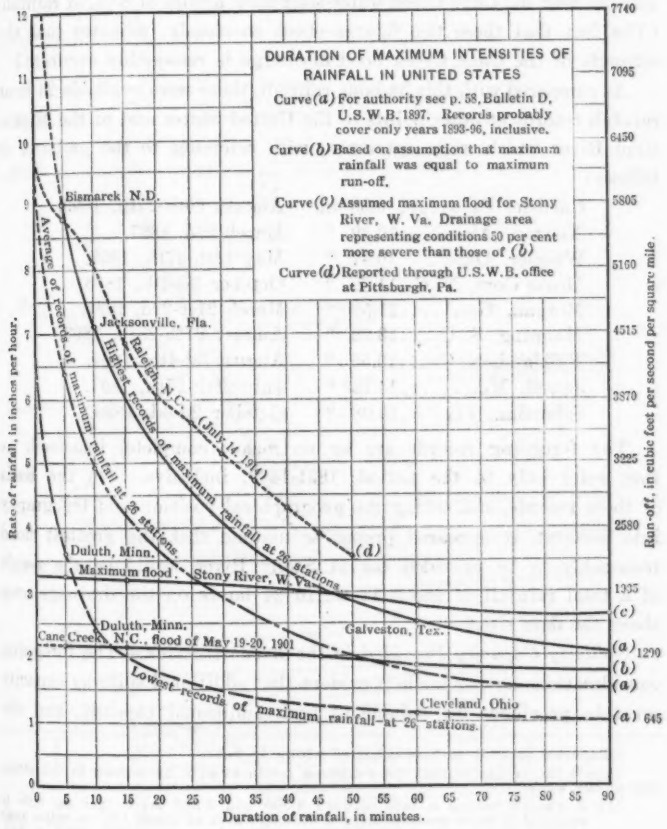

FIG. 9.

it is apparent that the rainfall which caused the Cane Creek flood was by no means as great as may be expected in either the Cane Creek or Stony River localities. This conclusion is confirmed by a study of the total rainfall in 24 hours.

The total run-off, as shown in Fig. 12, for the 24-hour period beginning at 7 P. M., May 19th, 1901, is equivalent to a depth of 7.48 in. over the whole Cane Creek drainage area of 22 sq. miles. For the same period it is reported that records at precipitation stations reasonably near the Cane Creek water-shed show a total of 8 in. of rainfall. (The fact that these two figures check so closely indicates that the estimate of the Cane Creek flood discharge is reasonably accurate.)

As compared with this 24-hour rainfall, there were available 24-hour rainfall records at other points in the United States east of the Mississippi River which were instructive with reference to the problem, as follows:

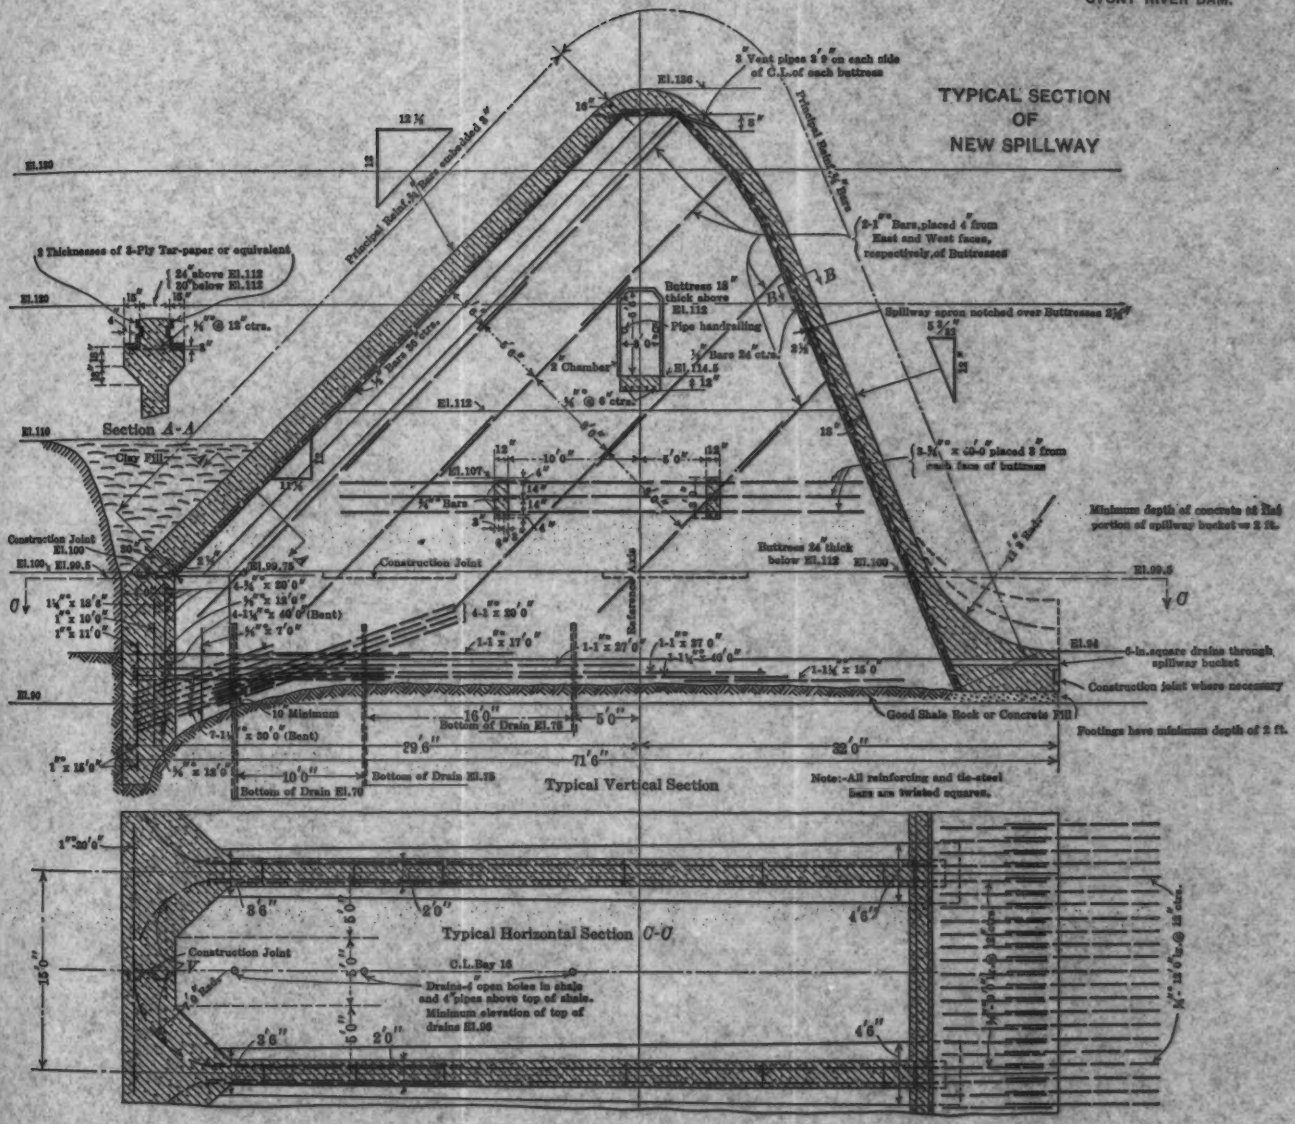
Carlisle, Pa.....	9.35 in.	August 26th-27th, 1899.
Newton, Ala.....	10.29 "	March 22d, 1897.
Wheeler, Ohio.....	10.47 "	May 16th-17th, 1893.
Horse Cove, N. C..	11.00 "	October 3d-4th, 1898.
Morgan, Ga.....	11.52 "	March 21st-22d, 1897.
Manning, S. C....	13.22 "	August 27th-28th, 1893.
Falkland, N. C....	13.55 "	August 3d-4th, 1894.
Jewell, Md.....	14.75* "	July 26th-27th, 1897.
Sebastian, Fla....	19.08 "	October 2d-3d, 1899.

The foregoing records are by no means complete, inasmuch as they refer only to the period, 1891-1899, inclusive. On the basis of these records, and taking the geographical position and topography into account, it appeared proper to assume that the greatest flood reasonably to be provided for at Stony River would be the result of a total rainfall of about 12 in. in 24 hours on the drainage area above the dam site.†

Spillway Capacity Provided in the Reconstruction.—The foregoing considerations having made it evident that additional spillway capacity must be provided, the volume of such additional capacity, and the

* Reported actually to have occurred within 18 hours.

† Since the reconstruction, the following pertinent data have come to the attention of the writer:



(1) A run-off having a rate between 2 000 and 2 333 sec-ft. per sq. mile is reported to have occurred over a drainage area of about 1½ sq. miles near Le Roy, N. Y., in May, 1916. *Engineering News*, June 24th, 1916, p. 842.

(2) For July 8th, 1916, Professor Alfred J. Henry, U. S. Weather Bureau, reports that the area (Alabama and Georgia) covered by a 24-hour rainfall of 8 in. and more was about 4 945 sq. miles. *Monthly Weather Review*, August, 1916, p. 467.

(3) A 24-hour rainfall of 22.22 in. is reported to have occurred on July 15th-16th, 1916, at Altapass, Mitchell County, N. C. (Elevation 2 625). *Ibid*, p. 467.

(4) It is reported that rain fell at the rate of 5.21 in. per hour for 25 min. at Mobile, Ala., on July 8th, 1916. *Ibid*, p. 468.

SCHEIDENHELM ON
RECONSTRUCTION OF
STONY RIVER DAM.

means of providing it, remained to be determined. No attempt will be made in this paper to discuss the alternatives considered for increasing the original spillway capacity of the dam, for such alternatives differed essentially only as to the extent to which the several available factors were utilized. Instead, the conditions caused by the maximum flood within the limits of reason will be applied to the means finally adopted for increasing the spillway capacity, in order to test the adequacy of these means. The adopted spillway provision, which will be understood by reference to Plate IX, was obtained by the following means:

1.—Reconstructing that portion of the original bulkhead section of the dam between Buttresses 10 and 19 to form a second spillway. The transverse cross-section of this new spillway is shown in Plate X. It was provided with a suitable reinforced concrete channel mat extending about 85 ft. down stream from the bucket of the spillway apron.

2.—Adding 3 ft. 6 in. to the height of the original bulkhead portions of the dam outside of the spillways, *viz.*, east of the old spillway and west of the new spillway. This was accomplished by adding a parapet, of the form shown in outline in Plate XII, with its top at Elevation 142.5.

3.—Increasing the height of that portion of the original bulkhead section of the dam between Buttresses 19 and *A* (*viz.*, between the old and new spillways) by the addition of a parapet 1 ft. high. This forms an intermediate spillway with its crest at Elevation 140, as shown in the typical sections of Plate XII.

4.—Utilizing the horizontal upper member of the new anchoring wall at the toe of the dam, between the old and new spillways, to form a reinforced concrete mat or "tumbling hearth" to receive the impact of the sheet of water falling well-nigh vertically from the intermediate spillway. This horizontal mat, together with an inclined, reinforced concrete, protection mat (section *B-B* of Plate XII), forms a channel sloping downward from the ends of the intermediate spillway section toward, and discharging through, a new outlet channel which extends down stream from Gate-bays 30 and 31.

5.—Improving the shape of the crest of the original or "old" spillway. This warranted the assumption of a somewhat higher coefficient of discharge, as applied in the Francis formula.

Under the original conditions, disregarding wave action, overtopping of the dam would have occurred when the water level in the reservoir had reached Elevation 139; whereas, under the conditions obtaining after reconstruction, overtopping cannot occur until the water level reaches Elevation 142.5. It is probable that overtopping due solely to wave action would be of minor consequence. However, as will presently be shown, the water level due to the greatest flood reasonably to be provided for would probably leave a margin of about 6 in. below Elevation 142.5.

Maximum Flood Within Limits of Reason.—For the purpose of studying the effect of such a flood, in the case of the Stony River Dam and Reservoir, let it be assumed that it would have a graph similar to that shown in Fig. 13. This graph was derived by increasing the rates of run-off shown in Fig. 12 by 50%, thus corresponding to the ratio of the estimated maximum 24-hour precipitation to the 8-in. precipitation reported to have occurred within a like period in the case of the Cane Creek flood. It is true, of course, that no two rain storms or floods are exactly alike; yet, for the purpose in mind, the foregoing assumption appeared to afford a reasonable basis for design.

For purposes of comparison, there has been plotted on Fig. 9 a curve (*c*) showing the rainfall for the critical 90-min. period of such assumed greatest possible flood discharge, the curve being based, as before, on the assumption (not strictly true) that the rate of rainfall would be equal to the rate of run-off. Even allowing for the evident equalization, or smoothing-off of the peak of the rainfall, it is apparent that a rainfall causing a flood such as that represented by the curve (*c*) would not equal certain actual records of rainfall.

Equalization Effect of Reservoir.—In studying the results of such floods as those plotted on Figs. 12 and 13, when applied to the Stony River drainage area and spillway provision, it may reasonably be assumed that in each instance there would be, initially, one point of time when, for all practical purposes, a state of equilibrium would exist.

At such a time the total run-off from the drainage area and the discharge over the spillway would be equal. Thereafter, as the run-off increased, a certain quantity of water would be stored over the whole reservoir area for each foot of rise in water level. The extent of such equalization or absorption would depend on the spillway capacity and the reservoir area.

The capacity of the reservoir above the elevation of the lower spillway crests is shown on Fig. 10. On Fig. 11 is plotted the spillway capacity (after reconstruction), derived from the data and assumptions there shown.

On the basis of these diagrams, the equalization effect of the reservoir has been studied with reference to a number of flood conditions, as follows:

I.—Before considering the greatest flood reasonably to be anticipated, it appears proper to study the equalization effect of the reservoir on a flood exactly similar, and equal in intensity, to that reported for Cane Creek on May 19th-20th, 1901. The result of such study is shown in Fig. 12. The spillway crests are assumed to be without flash-boards.

The method of deriving the curve showing the discharge over the spillways is as follows: Referring to Fig. 12, it is assumed that at 7 A. M. the total run-off from the drainage area and the discharge over the spillways are equal. The graph of the flood then shows that at this time the run-off would be approximately 100 cu. ft. per sec., which (from Fig. 11) would require the reservoir water level to be at Elevation 136.2. The effect of the storage capacity of the reservoir at increasing elevations of head-water is then determined at arbitrary intervals, depending on the refinement desired. Selecting a 0.3-ft. rise in water level as the first interval, it is found from the reservoir capacity curve of Fig. 10 that for this interval the reservoir will absorb approximately 39 000 000 gal. This quantity, when converted into the proper units and scale, is represented in Fig. 12 by the area, *a-b-c, viz.*: The point, *b*, of course, must have an ordinate representing the spillway discharge at Elevation 136.5, approximately 365 cu. ft. per sec. (from Fig. 11). The position of the line, *b-c*, is then determined by trial, the required area, *a-b-c*, having been determined as above stated.

FIG. 11.

Similarly, a 0.5-ft. rise in water level may be selected for the next interval. When the head-water has reached Elevation 137.0, the spillways will be discharging approximately 1 030 cu. ft. per sec. (Fig. 11), thus determining the ordinate of the point, *e*, of Fig. 12. Meanwhile, approximately 66 000 000 gal. (Fig. 10) will have been stored in the upper 0.5-ft. depth of the reservoir, thus determining the area, *b-c-d-e*, and hence the position of the line, *e-d*. By repeating this process, the curve of Fig. 12 representing "Discharge over spillways" is defined. The last interval—that between the points, *f* and *g*—must be determined by trial so as to utilize exactly the absorption capacity of the reservoir corresponding to that interval.

It is evident that the ordinate of the point, *g*, represents the spillway capacity necessary to pass safely the particular flood under investigation. In point of time, *g* represents the crest of the discharge over the spillways, though, in this instance, the crest of the spillway discharge does not occur until approximately 35 min. after the flood itself has reached its peak. From Fig. 12 it is seen that the maximum head-water level attained under the assumed conditions would be at Elevation 140.36. The corresponding discharge over the spillways would be approximately 9 600 cu. ft. per sec., whereas the available spillway capacity, with head-water just at the top of the bulkhead section parapets, is approximately 21 000 cu. ft. per sec. This appears to be more than ample margin, but it must be remembered that the graph of Fig. 12 represents a flood which actually occurred on the Cane Creek drainage area—approximately twice as great as that of Stony River at the dam site.

The crest of the discharge over the spillways having passed, the reservoir begins to yield the water which has been temporarily stored in that portion of the reservoir above the spillways. Therefore the discharge over the spillways continues to be in excess of the run-off, until finally the condition of equilibrium between spillway discharge and run-off is again reached. The descending portion of the curve, showing "Discharge over spillways," was derived by the same method as the ascending portion.

II.—Turning now to the consideration of the maximum flood within limits of reason, Fig. 13 shows the equalization capacity of the reservoir as affecting a flood exactly similar to, but with a unit discharge 50% greater than, the 1901 Cane Creek flood. The required

FIG. 12.

spillway capacity, derived by the method just described, is approximately 15 600 cu. ft. per sec., with the corresponding head-water at Elevation 141.6. Even though we accept the flood represented in Fig. 13 as being the maximum within limits of reason, the margin, or surplus spillway capacity, does not appear to be unreasonably large when it is remembered that this flood is essentially an arbitrary conception, and that, furthermore, it is subject to variations such as will now be considered.

III.—As will appear later in more detail, flash-boards about 3 ft. high (Plate IX) have been mounted on both old and new spillway crests, the tops of the flash-boards, therefore, being nearly at Elevation 139. The flash-board supports have been designed so as to fail and absolutely clear the spillway crest when the head-water level reaches an elevation between 140 and 140.5. It is proper, however, to consider the contingency that the supports might not fail with so low a head-water level as is intended. The diagram, Fig. 14, therefore has been prepared under the assumption that, with the same flood as that treated in Fig. 13, the flash-boards do not fail until the water in the reservoir reaches Elevation 141, namely, 5 ft. higher than the main spillway crests and 1 ft. higher than the crest of the intermediate spillway.

In this case the initial state of equilibrium would exist with head-water at about Elevation 139.3, that is, 0.3 ft. above the assumed top of the flash-boards. The effect of the initial rise of head-water (to Elevation 141.0) is determined in the same manner as described previously. With the breaking of the flash-board supports, however, and the consequent sweeping away of the flash-boards when Elevation 141 is reached, the discharging capacity of the spillways is suddenly increased—as is evident from the diagram—to such an extent that, temporarily, the discharge over the spillways is greater than the run-off from the drainage area. This, of course, would not necessarily be the case with a flood having a graph of different shape. The position of the point, *c*, was determined by trial, the area, *a-b-c*, representing the quantity of water stored in the reservoir in the depth interval between points, *c* and *a*, because this quantity must be yielded by the reservoir before the head-water can recede to approximately Elevation 140.52 at the point, *c*. Actually, *a-c* would undoubtedly not be a straight line; a more accurate location would be obtained by

Run-off and spillway capacity, in thousands of cubic feet per second.

FIG. 13.

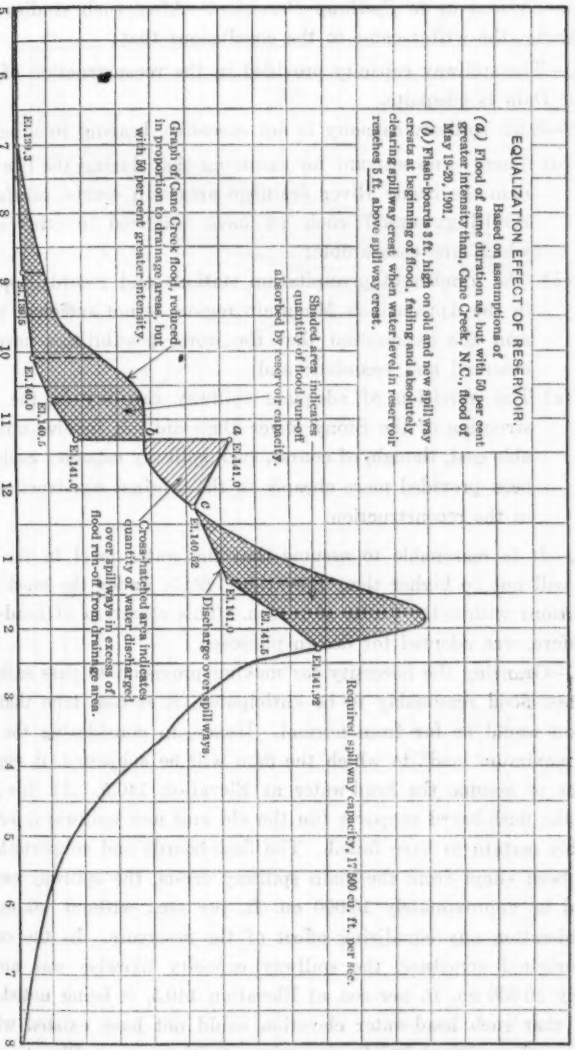
the determination of intermediate points, though the difference in final result would be slight.

The highest water level reached under the assumed conditions is at Elevation 141.92, with a corresponding discharge over the spillways of 17 500 cu. ft. per sec., which is still well within the available spillway capacity.

IV.—Again, it is true that the equalization of the peak of the rainfall, as compared with that of the run-off, would not necessarily be as great as in the case of the floods shown graphically on Figs. 12 to 14; and, though the writer does not consider it reasonable to assume that the Stony River Dam will be subject to conditions resulting from more than approximately a 12-in. rainfall occurring within 24 hours, yet, thus far, only one of an infinite number of graphs has been considered, any one of which would yield the same total run-off during the 24-hour period in question. The use of graphs having other shapes (but enclosing the same area) might increase or decrease the proportion of the available spillway capacity which is necessary to pass the corresponding flood.

Only one variation will be considered, for which see Fig. 15. It appears to be not reasonably conceivable that a flood resulting from a 12-in. precipitation in 24 hours (and yielding almost as much total run-off within the same period) could reach its peak and recede therefrom more quickly than that there represented. In order to make the severity of the assumed conditions more clear, the ordinates have been shown in terms both of run-off, in cubic feet per second, and of rainfall, in inches per hour. On the latter basis, these conditions may be compared with the records shown on Fig. 9. For instance, if, taking into account the time necessary for water to reach the dam site from the most remote portions of the drainage area, it is assumed that the peak of the run-off at the dam is equal to the greatest average rate of rainfall during any 45-min. period, then it is evident that, in order to cause the flood in question, it would have had to rain for 45 min. at an average rate of about 4 in. per hour. Such a rate corresponds approximately to the highest record plotted on Fig. 9.

Even under the severe, if indeed not improbable, conditions represented in Fig. 15, the head-water would reach a maximum elevation of only 142.05, with a corresponding discharge over the spillways of approximately 18 300 cu. ft. per sec.



EQUALIZATION EFFECT OF RESERVOIR.
Based on assumptions of
(a) Flood of same duration as, but with 50 per cent greater intensity than, Cane Creek, N.C., flood of May 19-20, 1901.
(b) Flash-boards 3 ft. high on old and new spillway crests at beginning of flood, failing and absolutely clearing spillway crest when water level in reservoir reaches 5 ft. above spillway crest.
Required spillway capacity, 17,500 cu. ft. per sec.
Shaded area indicates quantity of flood run-off absorbed by reservoir capacity.

FIG. 14.

Conclusions as to Spillway Provision.—After such studies as the foregoing, the writer came to the conclusions that:

1.—The spillway capacity provided in the reconstruction of Stony River Dam is adequate.

2.—Such spillway capacity is not excessive, bearing in mind that:

(*a*) There is no warrant for assuming that during the life of the dam the Stony River drainage area will escape rainfall and resulting run-off such as have occurred in other regions which are comparable;

(*b*) The number of precipitation stations and records, especially in the Appalachian Mountain region, is not sufficient to warrant the assumption that the worst possibilities have been observed and recorded; and

(*c*) The provision of adequate spillway capacity in the reconstruction of the Stony River Dam did not involve unreasonable cost, though, of course, such spillway capacity could have been provided more cheaply in the original construction than in the reconstruction.

3.—It is reasonable to assume that the water level in the reservoir will not be higher than Elevation 142.25, under the most severe conditions within the limits of reason. This elevation of head-water, therefore, was adopted for design purposes.

4.—Granting the necessity for making provision to pass safely the greatest flood reasonably to be anticipated, it is also true that such a flood would be far from normal. Hence, in considering the "normal maximum load" to which the dam will be subjected, it appeared proper to assume the head-water at Elevation 140.5. At this elevation the flash-board supports (on the old and new spillways) are reasonably certain to have failed. The flash-boards and supports having thus been swept from the main spillway crests, the spillway capacity would be approximately 10 000 cu. ft. per sec., without taking into consideration any equalizing effect of the reservoir. In the case of the original structure, the spillway capacity likewise was approximately 10 000 cu. ft. per sec. at Elevation 140.5, it being noted, however, that such head-water elevation could not have existed without causing the original bulkhead sections (with crest at Elevation 139) to be overtopped. The corresponding unit spillway capacity is about 875 cu. ft. per sec. per sq. mile of drainage area.

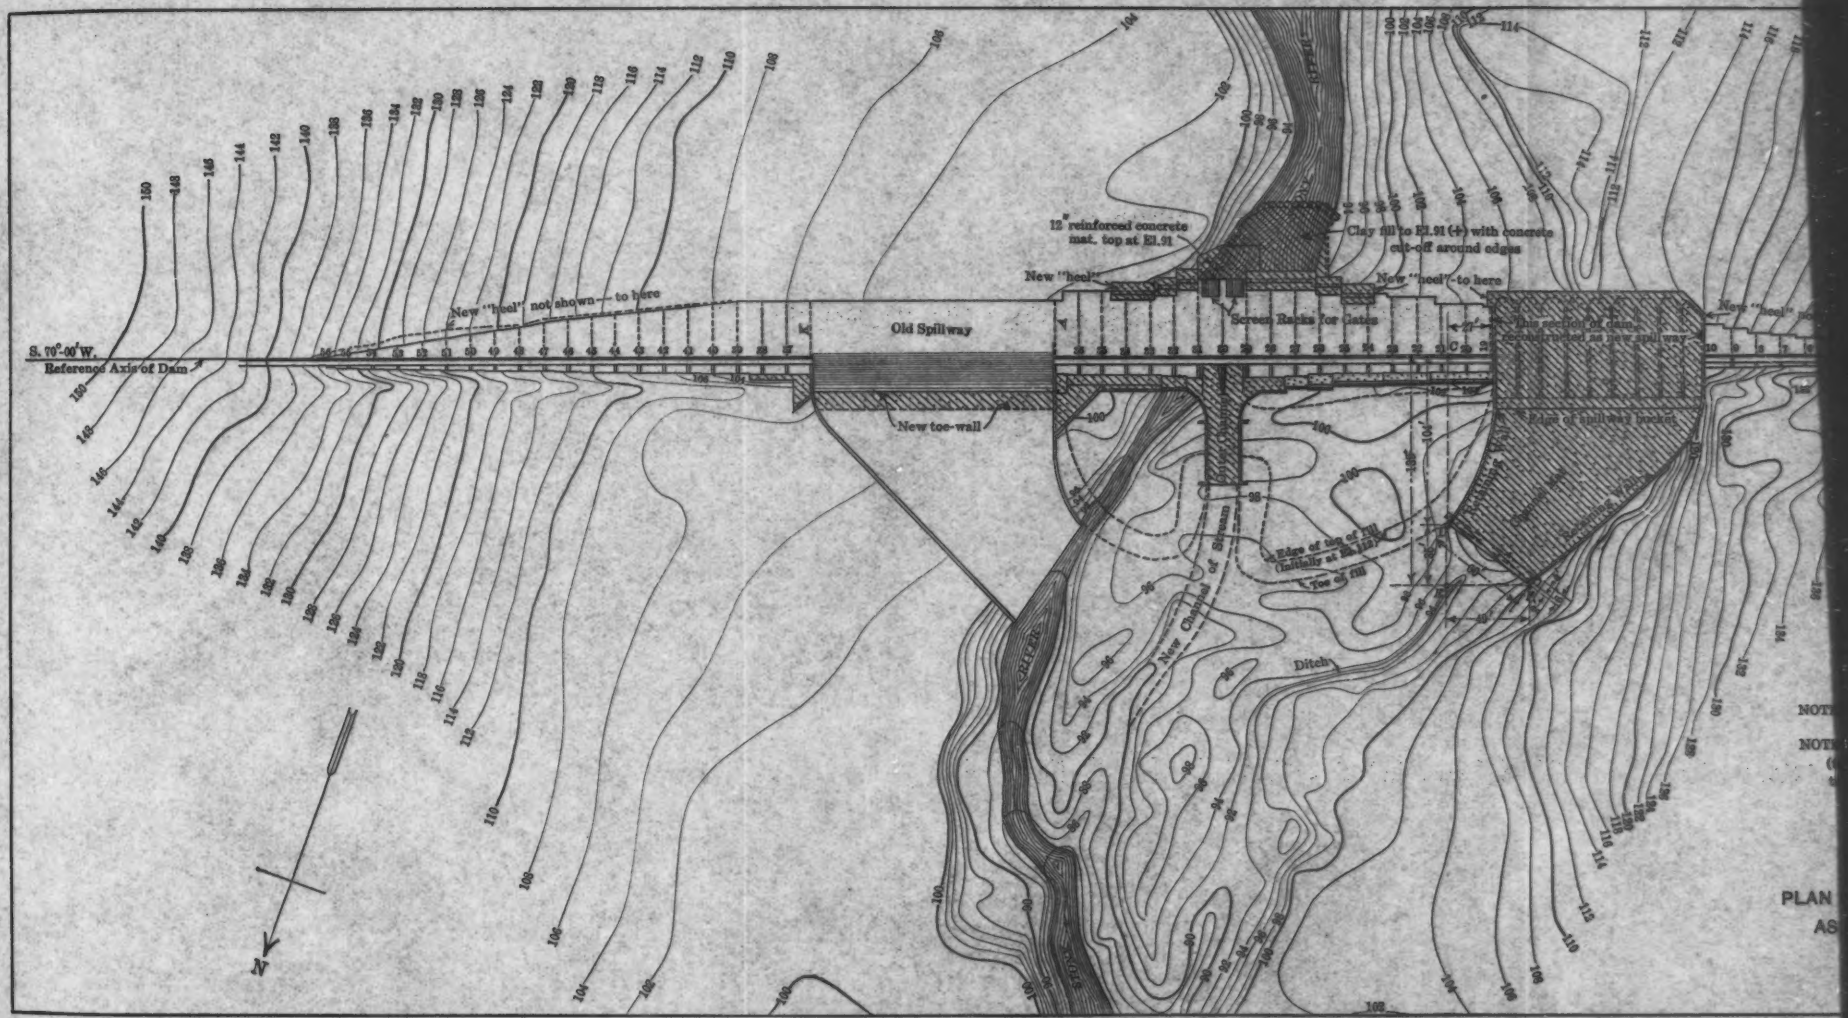

FIG. 15.

Type of Structure for New Spillway.—It appeared logical to reconstruct the new spillway section of the dam according to the Ambursen, hollow, reinforced concrete type, provided there was no serious and valid counter consideration. Probably the most serious questions in regard to the Ambursen type of dam are those dealing with the protection of the embedded reinforcing steel from corrosion, and the extent to which the dimensions of the reinforced concrete members may properly be pared down to theoretical limits. Both these questions may be answered satisfactorily, so the writer thinks, by a sufficiently conservative design of the members of the structure.

On the other hand, the advantage of economy lay with the hollow, rather than with the solid, type, a by no means unimportant factor being the relatively high cost of the materials composing the concrete. For equal margins of safety, a solid dam would have involved somewhat greater quantities of concrete, although probably not of excavation. Furthermore, the construction of a solid section at the new spillway would have caused difficulties, costly to meet, at Buttresses 10 and 19 by reason of subjecting those buttresses to lateral hydrostatic pressure for which they were not designed.

In view of its secluded location, the appearance of the structure is of relatively minor importance. Yet even this consideration argued in favor of the hollow type, because, at least on the up-stream side, the solid section would have caused an incongruous break in outline.

Connecting with the foot of the new spillway apron, a channel mat was constructed which gradually narrowed to a width of 60 ft. at a distance averaging about 85 ft. down stream, as shown in Plate XI. The minimum depth of the channel mat varies from 30 in. on clay (24 in. on rock) at the foot of the spillway apron to 18 in. at the down-stream end of the mat, where a shallow cut-off wall seals the mat into bed-rock. Reinforced concrete retaining walls (Figs. 16 and 17) were built along the sides of the channel mat, to support the hillside on the west and the new fill between the spillways on the east. Excavation of the new spillway channel was not completed down stream from the channel mat. Only a small ditch was dug to drain water from the channel mat into the river, and the first flood practically completed the remainder of the excavation necessary to furnish sufficient connection between the new spillway and the river.

RECONSTRUCTION OF
STONY RIVER DAM.

PLAN OF STONY RIVER DAM
AS RECONSTRUCTED

STONY RIVER DAM AFTER RECONSTRUCTION.

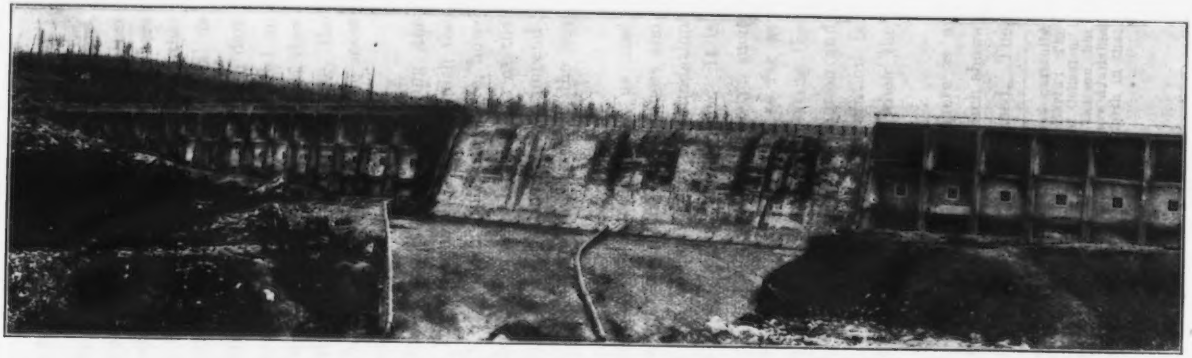

FIG. 16.—EASTERN PART, SHOWING OLD SPILLWAY.

FIG. 17.—WESTERN PART, SHOWING NEW SPILLWAY.

Resistance to Sliding.

To the writer it appears that, in the case of many masonry dams, solid and hollow, the importance of safeguarding the structure against failure by sliding has been under-rated. It is not unlikely that there have been more failures of masonry dams by sliding than in any other manner. The character of the underlying foundation material is necessarily the primary factor controlling the stability of a given dam in regard to sliding. The construction of a dam to be founded on granite, for instance, offers no difficulties in this respect. But, in view of the foundation material underlying the Stony River site, the necessity of making the dam safe against sliding presented the most important problem of the reconstruction.

Uplift pressure, too, is of great importance as affecting the stability of a dam against sliding. It acts essentially to diminish the weight of the structure. The effect of a given uplift pressure, however, depends largely on the coefficient of frictional resistance of the foundation material at the plane along which sliding may be impending; that is, the smaller the coefficient of frictional resistance, the less the net effect of the uplift pressure.

Frictional Resistance.—The term "frictional resistance", as used in this paper, is intended to express both the effect of roughness and the effect of adhesion between any two bodies (*e. g.*, of foundation material) at the surfaces along which sliding is taking place. It is not intended to express the effect of cohesion within a body; such cohesion is an additional factor resisting sliding, and, in so far as resistance to sliding is concerned, must be overcome by shearing the body in question.* The distinction here made between adhesion and cohesion does not exist when the material under consideration is viscous, but, in the writer's opinion, it exists definitely when the material in question is solidified.

As to the actual coefficients of frictional resistance, there is a woeful dearth of data. Attention is called first to Table 1 which shows the assumptions on which the reconstruction design was based. The

* Since the reconstruction was completed, the writer has considered carefully the paper by William Cain, M. Am. Soc. C. E., entitled "Cohesion in Earth: The Need for Comprehensive Experimentation to Determine the Coefficients of Cohesion", *Transactions*, Am. Soc. C. E., Vol. LXXX, p. 1315, and the discussions thereon, but has been unable to agree that data, sufficient in number and reliability, are available to warrant the use, especially in the present case, of the analysis set forth in that paper.

TABLE 1.—COEFFICIENTS OF FRICTIONAL RESISTANCE FORMING THE BASIS OF DESIGN IN THE RECONSTRUCTION OF STONY RIVER DAM.

Character of foundation material.	Value assumed for design.	Probable minimum value.	Ratio.
Clayey overburden—wet..... Applying to footings of the original sections of dam and to probable "planes of least resistance" in clayey foundation soil.	0.33	0.25	0.75
Shale with clay seams..... Applying to shale near surface of bed-rock; hence including shale immediately underlying new footings at Buttresses 10 to 19, inclusive (new spillway section.)	0.40	0.25	0.625
Hard shale, not disintegrated..... Applying to shale at probable "planes of least resistance" at Buttresses 10 to 19, inclusive (new spillway section.)	0.50	0.40	0.80

"planes of least resistance" referred to in that table are explained later.

The pertinent data considered in adopting these assumptions follow.

Frictional Resistance of Clayey Soil.—In the writer's opinion, the safe coefficient of frictional resistance for the clayey foundation soil at the dam site when wet is between 0.3 and 0.4. When such soil is dry or merely moist, the frictional resistance, of course, is greater than when it is thoroughly wet; but it is not safe to assume that the foundation soil will always be fairly dry. It is true that the leakage from the reservoir into the foundation soil has, at this writing, become, and in all probability will continue to be, a relatively minor factor. However, ground-water in the soil cannot be disposed of, especially inasmuch as the dam site receives the ground-water drainage of the adjoining hillsides. The new drainage system of the dam cannot cause the foundation soil to become dry. It can merely prevent the accumulation of serious uplift pressure.

The results of various tests of frictional resistance are of record. Unfortunately, they are not numerous; nor are the test conditions sufficiently standardized, nor the character of the material under tests sufficiently well defined, to allow satisfactory detailed comparison with each other or with the conditions to which it is attempted to apply their results. Moreover, it is the rule, rather than the exception, that, as in the case in point, the foundation material is heterogeneous, thus increasing the difficulty of drawing comparisons with previous test

results and making more necessary the use of judgment in selecting coefficients for design or other purposes.

Among the recorded data are the experiments of General Morin, as referred to by Rankine,* which indicate a coefficient of frictional resistance of 0.31 for wet clay on wet clay, as tested by him. Tests of the foundation soil in question, however, are more pertinent, and such tests were made on several kinds of soil by Mr. D. N. Showalter, Resident Engineer, under the direction of the writer. The results of these tests are given in Table 2.

In the ordinary case, these tests were made by tamping a given kind of soil into a box having an open top, the box being a cube of about 12 in., then capping the boxful of soil with a solid piece of the same material, so that it protruded above the edge of the box, and turning the box upside down. The protruding material, after having been given an approximately horizontal surface and made smooth, was utilized as the moving element in determining the frictional resistance on a prepared, smooth, horizontal bed of the same kind of material in place. The moving element was drawn along by hand over the bed, the required pull being measured by a spring balance. Ordinarily, more than $\frac{1}{2}$ sq. ft. of the material under test was actually in contact. The method of making the tests is illustrated by Figs. 8 and 18.

In the case of the tests made in cold weather, the clay bed had been scraped previously so as to remove all frozen material and any "mud" formed by melting snow. When not under test, the surface or bed was protected by a covering of tar-paper. In the last series of tests, in May, 1915, a galvanized-iron pail was used instead of a wooden box. The result was to make these experiments appear even more crude than was really the case; but, inasmuch as the weight of the moving element and the required pull were not less readily determinable, such experiments are not believed to be the less worthy of consideration.

Despite the absence of laboratory refinements, the results obtained are in all probability reasonably indicative of the actual frictional resistance, as previously defined. Among the results of any single group of experiments, the maximum variation from the mean was 30% of the mean, and the average of such maximum variation for all

FIG. 18.—TEST OF FRICTIONAL RESISTANCE.

FIG. 19.—DEEP DRAINS.

groups was about 15 per cent. The series of tests was not sufficiently extensive to warrant any conclusions as to variations in the coefficient of frictional resistance with variations in the load or in the velocity of the moving element.

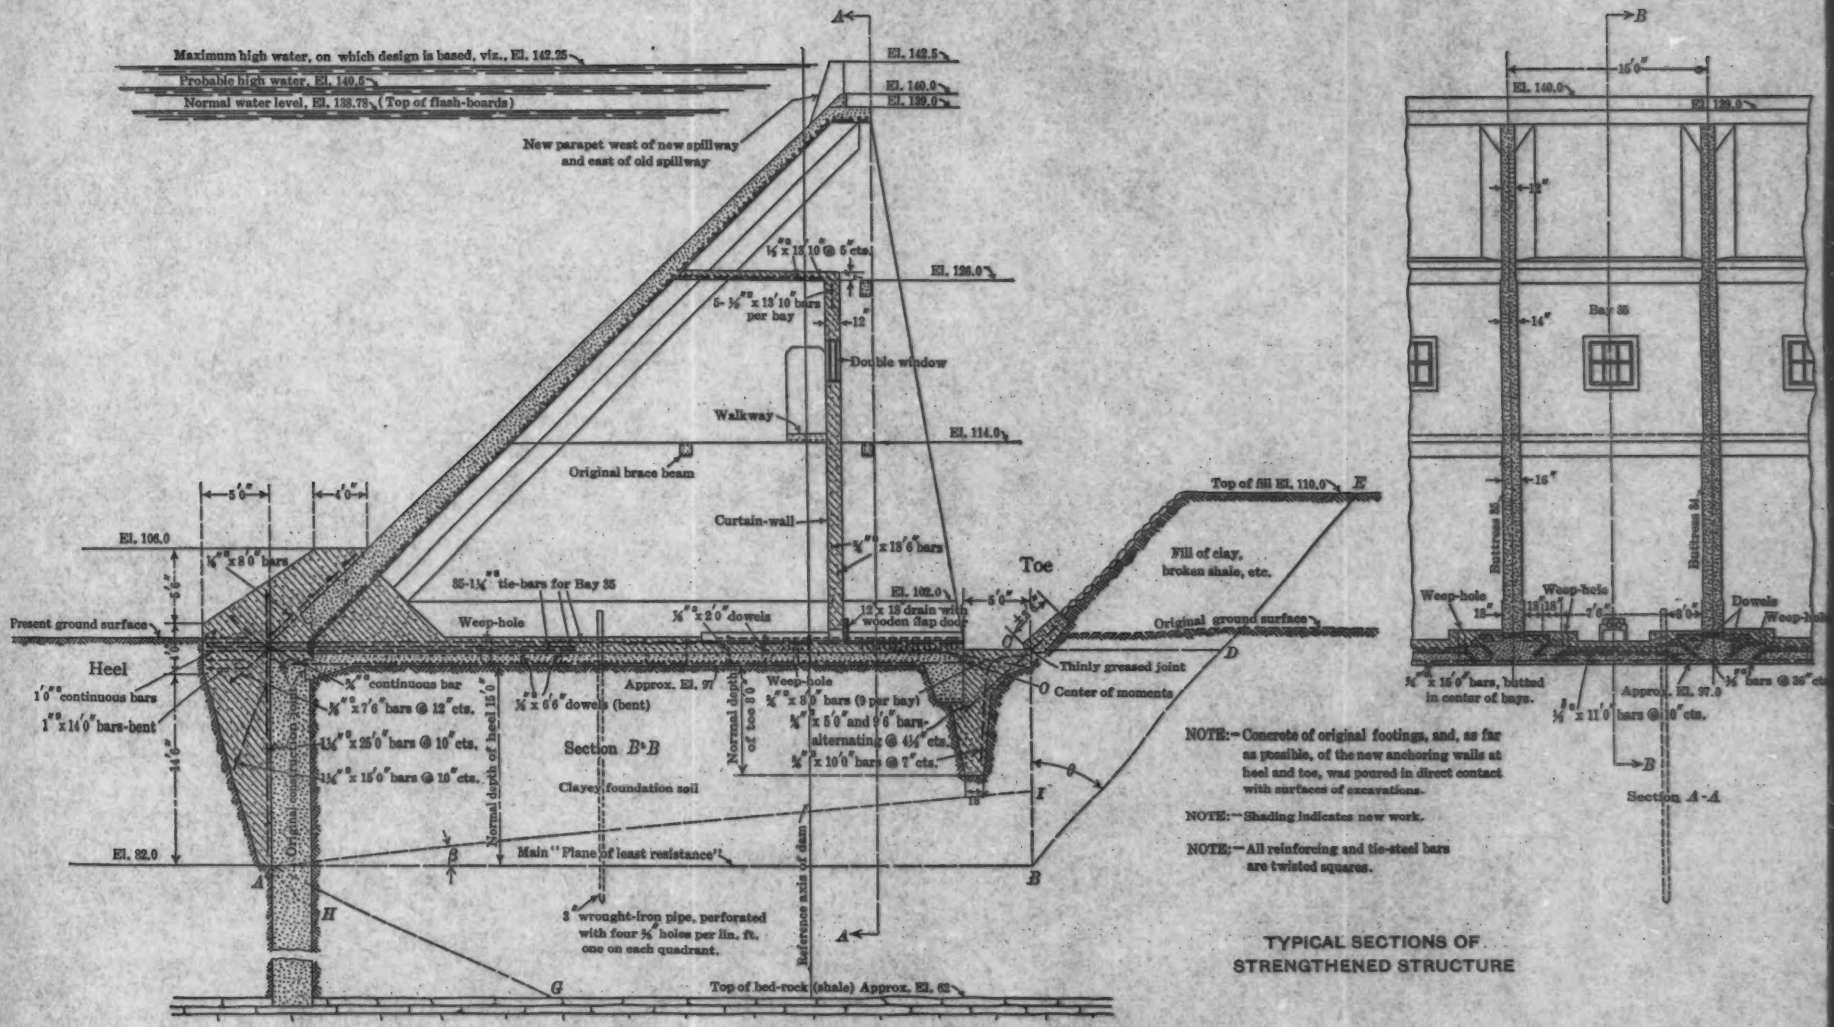
The pull or force required to start the load in motion has not been shown in Table 2, for it is believed that, in order to make a reasonably close determination of the starting force, greater refinements are necessary than could be applied in the field experiments in question. It should be noted, however, that, in view of the method of testing used, the shearing resistance (due to cohesion) of the material under test was not brought into play.

The average of the results of all the experiments shows a coefficient of frictional resistance, including adhesion, equal to about 0.61. This figure, however, affords no reliable index, as is apparent from the wide variation in values corresponding to the different kinds of soil tested. The interpretation of the results as applying to design, therefore, is essentially a matter of judgment. The variations referred to are so great that the only safe course was to assume that the worst soil conditions (as regards frictional resistance) might exist under any bay. East of Buttress 36 (Plate IX) the clayey content of the overburden was somewhat greater than west thereof, and hence it seemed reasonable to assume that there the soil is less subject to percolation and has a somewhat greater bearing value. Nevertheless, no modification was made in the matter of frictional resistance on this account.

The coefficient of frictional resistance for the clayey foundation soil (wet) was, for design purposes, finally assumed to be 0.33. The writer believes that for none of the soils at the dam site is the corresponding coefficient less than 0.25.

Frictional Resistance of Shale.—Here, again, there are but few data available; perhaps the most pertinent are those given by Mr. E. L. Lasier in his article on "Tests of Frictional Resistance of Concrete on Shale."* These tests were made under the direction of the writer at the site of the State Line Dam of the Hydro-Electric Company of West Virginia, on Cheat River, in West Virginia, and cover, not merely the frictional resistance of concrete on shale, but also that of shale on shale.

* *Engineering News*, July 22d, 1915.



At the Stony River dam site the shales have pronounced horizontal laminations.* Hence the results in Mr. Lasier's Table 1 apply, the tests summarized in that table having been made on quarried blocks of shale. There the coefficient of frictional resistance for the shale specimens moving on the stationary shale blocks averaged 0.61 when the surfaces in contact were dry, and 0.55 when they were wet. In view of the apparent differences in physical characteristics, it seemed proper to adopt assumptions even more conservative than those shown in Mr. Lasier's tests. This is especially true as regards those Stony River shales near the surface of bed-rock. Inasmuch as these had been exposed to disintegration ages ago, clay seams or laminations had been formed. The coefficients adopted are given in Table 1.

Stability of Original Structure Against Sliding.—The stability of a dam against failure of a given kind is ordinarily measured by its so-called factor of safety—which perhaps may be more correctly termed its "ratio of safety". This is the ratio of the forces resisting failure in a certain manner to the forces tending to cause such failure; but, whether or not a ratio of safety really means anything depends on the assumptions made in deducing that ratio; and, as previously suggested, it is seldom that two engineers working entirely independently arrive at exactly the same results as regards the ratio of safety. The writer makes it a practice to study the stability of a structure under several different sets of assumed conditions. Sometimes, too, after having ascertained the ratio of safety under the conditions to which it appears a dam will be subjected, it is instructive to see how severe, perhaps even how unreasonably severe, the conditions can be made without reducing the ratio of safety below unity.

In the present instance the stability of the dam was examined under the assumption of a "normal maximum load" and also under the "most severe conditions within the limits of reason", all, of course, as they appear to the writer. These several load assumptions are set out in Table 3, for a typical section of the dam, *viz.*, at Bay 35 (Plate XII), and for the sections of maximum height, both on the basis of the original structure and also on the basis of the structure as strengthened during the reconstruction.

* Unlike the foundation shale at the Stony River site, the shales of the State Line site are not continuously laminated within themselves in any one plane. Hence the condition applying to the State Line site is more nearly that summarized in Table 2 of Mr. Lasier's article, which shows ratios of horizontal moving force to resistance to sliding (including resistance to shear in shale and concrete), the lowest of which is approximately 3.0.

(e) Coefficient of frictional resistance	0.33*	0.33*	0.25*	0.25*	0.33	0.33	0.25	0.25

* Resistance (to horizontal movement) on part of the original unreinforced cut-off wall and the original toe probably inconsiderable and treated as forming part of the frictional resistance of the foundation soil at the base of the footings.

NOTE.—No tail-water pressure in any case.

Referring to Table 3, it should be noted that, in connection with the question of frictional resistance, no attempt has been made in the case of the original structure to determine the additional resistance of the original cut-off wall and toe. Inasmuch as the cut-off wall was unreinforced throughout, and was not tied into the body of the dam except at a few places, it is believed that the resistance of the cut-off

wall to horizontal movement was not a reliable factor, and that, even when present, it was inconsiderable in amount. Likewise, the resistance of the original toe was probably negligible, because the toe was relatively shallow.

The assumed conditions of Table 3, in so far as pressure is concerned, are entirely arbitrary. In view of the fact that, both at the sections of maximum height and at the typical section of Plate XII, the strengthened structure has an adequate cut-off, it is certain, of course, that the uplift pressure actually does not decrease uniformly from heel to toe, as has been assumed. However, everything considered, and especially in the absence of definite knowledge regarding the presence and character of the uplift pressure, it appears reasonable to base stability analyses on assumed "equivalent" conditions of uplift pressure (see Table 3, factor (*d*)-2). Manifestly, uplift pressure could not be exerted over the entire area of the base without causing flotation, which is impossible.

I.—Under "Normal Maximum Load".—Applying now the assumed "normal maximum load" conditions of Column (2), Table 3, to the maximum height sections of the original structure, and stating all quantities for one bay 15 ft. wide, the results are as follows:

Weight of concrete	1 044 900 lb.
Weight of water on deck	1 194 500 lb.
Sum of loads	2 239 400 lb.

Total resistance to sliding, 2 239 400 lb. $\times$ 0.33 = 746 500 lb., approximately.

$$\frac{\text{Forces resisting sliding}}{\text{Forces tending to cause sliding}} = \frac{746\,500 \text{ lb.}}{1\,218\,200 \text{ lb.}} = 0.61.$$

Or, *vice versa,* in order that this ratio may become equal to unity, the coefficient of frictional resistance must equal

$$\frac{0.33}{0.61} = 0.54.$$

II.—Under "Most Severe Conditions Within Limits of Reason".—Referring to the assumed conditions of Column (4), Table 3, the spillway crest (Elevation 136) has been adopted as the highest elevation at which ice pressure could be present, because flash-boards could

hardly have been used with safety on the original spillway. Uplift pressure has been assumed as acting along the entire width of the base of the original structure (though over only 50% of the area), because in severely cold weather the weep-holes through the footings were frozen up solidly and hence were ineffective. With all quantities stated, as before, in terms of a 15-ft. bay, the results are as follows:

Weight of concrete	1 044 900 lb.
Water load on deck	985 500 lb.
Total downward pressure	2 030 400 lb.
Deduct uplift pressure	675 000 lb.
Net load	1 355 400 lb.
Total resistance to sliding = 1 355 400 lb. $\times$ 0.25 = 338 850 lb.	
Horizontal water pressure	1 219 200 lb.
Ice pressure	300 000 lb.
Total forces tending to cause sliding	1 519 200 lb.

Hence the ratio of safety is

$$\frac{338\,850 \text{ lb.}}{1\,519\,200 \text{ lb.}} = 0.223.$$

Or, in order that the ratio of safety against sliding may become equal to unity, the coefficient of frictional resistance must equal 0.25 divided by 0.223, *viz.*, 1.12. Evidently, therefore, the Stony River Dam as originally constructed could not be considered as having a reasonable margin of safety against sliding.

It would be interesting, of course, to know what coefficient of gross resistance to sliding obtained prior to failure. In order to derive the minimum value of such coefficient, the following assumptions are made, conforming to the conditions which actually existed, *viz.*:

(*a*) Head-water level at elevation of spillway crest, *viz.*, at Elevation 136;

(*b*) No ice pressure;

(*c*) Horizontal water pressure equivalent to full hydrostatic pressure of 46.5 ft., *viz.*, down to Elevation 89.5;

(*d*) Uplift pressure negligible;

(*e*) No tail-water pressure;

(*f*) Any resistance to horizontal movement furnished by the unreinforced cut-off wall or the toe-wall is treated as forming part of the gross resistance to sliding on the part of the foundation soil.

Under these conditions, the ratio of the force tending to cause sliding to the load above the base of the footings, for a 15-ft. bay, was

$$\frac{1\,013\,600 \text{ lb.}}{2\,030\,400 \text{ lb.}} = 0.50.$$

In other words, the coefficient of gross resistance to sliding, under the foregoing conditions, was at least 0.50; for, necessarily, the ratio of safety was at least unity.

Probably the resistance to horizontal movement, as expressed by such ratio or coefficient, was due in part to cohesion or resistance to direct shear within the foundation soil itself. That is, it is likely that failure would occur, not at the relatively rough surface of contact between the footing concrete and the foundation soil, but along an approximately horizontal plane in the body of the soil just below the base of the footings. Such resistance to shear will be discussed further in connection with the expedient adopted to increase the resistance to sliding in that portion of the dam which was not disturbed by the failure.

It should be noted that in the 65 days prior to the failure, during which period the dam withstood the pressure of the full reservoir, relatively cold weather obtained, and the ground-water was practically at its lowest level. In other words, it is likely that the frictional resistance would have decreased as the foundation soil became more saturated by leakage and ground-water during the following spring. Whether the dam would have stood, or how near it was to failure by sliding, no man can tell.

Means to Increase Resistance to Sliding.—Various expedients were considered for increasing the margin of safety of the original structure against failure by sliding. The method finally selected involved the construction of anchoring walls at the heel and toe of the original structure, essentially as shown on Plate XII, which shows typical sections of the dam, though not those of maximum height. In order to explain more clearly the reasons for adopting this method

of increasing resistance to sliding, the alternatives considered will be briefly described and their advantages and disadvantages stated.

1.—Referring first to the principal feature of the adopted means, the essential advantages of the anchoring wall at the heel (the action and construction of which are discussed in more detail later herein) are as follows (Plate XII):

(*a*) It utilizes the foundation soil under the dam, and in effect also a considerable quantity of the foundation soil immediately down stream from the dam, to increase the total weight which must be moved down stream in case the dam is to fail by sliding.

(*b*) The construction of such an anchoring wall at the heel seals the construction joint at the top of the original cut-off wall, this joint having in some places opened up sufficiently to allow appreciable, if not indeed serious, leakage.

(*c*) With such an anchoring wall, any down-stream movement on the part of the dam will tend to compact the underlying foundation soil, and, therefore, to make it less pervious.

(*d*) This was found to be the most economical method of obtaining the desired margin of safety against failure by sliding.

The only disadvantage of constructing an anchoring wall at the heel alone lay in the resulting high unit pressure against the clay immediately down stream from such "heel"—as the new anchoring wall at the heel of the dam has for convenience been styled.

2.—With especial reference to that portion of the original structure which remained intact, there was, of course, no opportunity to flatten the slope of the deck, and thus obtain a greater water load.

3.—The loading of the footings of the hollow structure, by using concrete, rock, or earth, was considered, and was rejected because:

(*a*) Such additional material would increase the load on the already too heavily loaded foundation soil;

(*b*) The original footings would have required even more strengthening than was considered necessary with the means finally adopted;

(*c*) Such loading would have required special provision for inspection of the drainage system; and

(*d*) The expedient was limited in extent, and, taken by itself, was not considered to be sufficient.

4.—Various structural additions at the toe of the dam were considered; among them an L-shaped anchoring wall such as that shown on Plate XII. This method of obtaining additional resistance to sliding was not open to the objections to the proposed loading of the original footings. However, if adopted to furnish the entire required increase in resistance to sliding, it would have been subject to certain different objections, *viz.*:

(*a*) For the same depth below original ground surface, generally speaking, less increase in resistance to sliding results than in the case of an anchoring wall at the heel alone; for the toe-wall does not utilize the foundation material under the body of the dam.

(*b*) In the case of this particular clayey soil, the toe-wall, like the "heel", is limited in efficacy by the safe bearing value of the soil in compression.

(*c*) In case of any yielding at the toe of the dam, either downward or down stream, the effect might be to cause either cracking in the original cut-off wall or, at the very least, the opening of the construction joint at the top of the old cut-off (Plate XII). Thus, water under reservoir pressure might immediately be admitted under the base of the dam.

On the other hand, the anchoring wall at the toe has certain advantages not possessed by the "heel", *viz.*:

(*d*) By means of its vertical member, the toe-wall confines the foundation soil under the original footings of the dam, thus increasing the safe load to which that soil may be subjected.

(*e*) The horizontal member of the toe-wall in effect increases the width of the base of the dam, thus decreasing the unit vertical load on the foundation soil, as will be shown later in more detail under the heading "Footings".

It is clear, however, that in cases where it is necessary similarly to increase the margin of safety of a dam against failure by sliding, but where there is no opportunity to construct an anchoring wall at the heel, an anchoring wall at the toe can be made to answer the purpose. Generally speaking, it is merely a matter of proportioning such a toe-wall properly.

5.—Investigation was made of the desirability of constructing reinforced concrete columns at the toe of the dam, inclining downward and approximately parallel to the line of action of the resultant load on the dam. This proposal was rejected, partly because the result would be equivalent to placing the dam on relatively unyielding supports—stilts, as it were—thus changing the character of the stresses in the original footings.

6.—The construction of a heavy block of concrete, approximately square in cross-section and extending along the entire length of the toe of the dam, was considered and rejected because the L-shaped toe-wall transmits vertical and horizontal loads into the foundation material to the same extent, but with much less concrete and excavation.

In view of the foregoing considerations, it was concluded to use anchoring walls at both heel and toe; for, by means of the toe-wall, it was possible to reduce to a safe value the otherwise excessive horizontal load on the foundation soil at the heel. The reconstructed dam acts essentially as a monolith; hence down-stream deflection or yielding must be equal at heel and toe. Inasmuch, then, as the load on the foundation soil is proportional to the deflection, the unit horizontal loads at heel and toe are approximately equal.

Likewise, at the new spillway of the dam, an anchoring wall at the heel was used. Here advantage was taken of the opportunity of combining the cut-off and the anchoring device in a single wall, as shown on Plate X. As the foundation of the new spillway consists of shale, the problem of keeping within the safe load against the material at the heel was not difficult, and hence no anchoring wall was required at the toe.

Analysis of Anchoring Walls.—The principle on which the design of the anchoring walls is based applies both in the case of the strengthening of the original structure and in that of the construction of the new spillway. The detailed explanation, however, will be made with reference to the typical bulkhead section at Bay 35, as shown on Plate XII.

The use of such anchoring walls, to furnish specific and reliable resistance to sliding, by utilizing the weight of the foundation material underlying, and immediately down stream from, a dam, is believed to be new. The writer first applied it in the case of the State Line Dam of the Hydro-Electric Company of West Virginia, on Cheat River in West Virginia.

Referring now to Plate XII, the anchoring wall at the heel is tied into the dam by twisted, square, steel bars extending through openings broken through the base of the original deck of the dam. The heel itself consists essentially of two cantilever members of reinforced concrete, extending, respectively, above and below the steel which ties the heel to the original structure. A relatively long cantilever member extends downward immediately adjacent to the up-stream face of the original cut-off, and a relatively short cantilever member extends upward immediately adjacent to the base of the original deck. Both cantilevers are suitably reinforced against stresses due to bending moment and shear.

Although some of the horizontal water pressure is exerted directly against the anchoring wall or heel, the greater portion is exerted against the deck, and by the deck is transmitted into the buttresses. The tie-steel previously referred to is embedded in the reinforced concrete footing strengthening, which in turn is thoroughly tied into the base of each adjacent buttress, as shown on Plate XII. Thus the tie-steel receives from the buttresses and the footings that portion of the horizontal water pressure which is not exerted directly against the heel, or has not been taken up by the frictional resistance of the foundation soil immediately in contact with the footings.

The lower cantilever member of the anchoring wall in turn transmits such surplus load into the foundation soil down stream from the heel. The fact that the stress is transmitted through the medium of the original cut-off wall is immaterial, except to the extent that the cut-off wall serves to transmit some of the load into the foundation soil below, and down stream from, the bottom of the heel. The reaction at the top of the lower cantilever, of course, is taken up by the upper and shorter cantilever and transmitted through the deck, in part directly into the buttresses and in part into the approximately triangular fillet of new concrete placed in the angle between the deck and the footings (Plate XII). Ordinarily, this fillet acts as an arch to transmit the reaction back into the buttresses and footings. In certain cases, however, where steps occur in the footings at the centers of bays, it was necessary to reinforce the triangular fillets to act as cantilever beams supported at the buttresses and extending outward to the centers of the adjacent bays.

The effect of the anchoring wall at the heel is essentially to lower the main "plane of least resistance" to sliding from its original posi-

tion, at or immediately under the base of the footings of the dam, to a position approximately at the elevation of the bottom of the new anchoring wall at the heel. By "plane of least resistance" to sliding is meant the surface or surfaces, approximating a plane or planes extending through the foundation material, along which the total resistance to horizontal movement (sliding) is less than along any other surfaces or approximate planes.

In so far as resistance to sliding is concerned, the result of such lowering of the main "plane of least resistance" is to cause the weight of the foundation material in advance of the anchoring wall to be utilized at least as effectively as the weight of the body of the dam itself. This utilization of the weight of the foundation material occurs in two ways, as will be apparent by reference to Plate XII. Let it be assumed that, for the conditions existing in the typical section there illustrated, the "planes of least resistance" are represented by the lines, *A-B* and *B-E*, respectively. Then

1.—The foundation material lying above *A-B* and to the left of *B-C* must, in case of failure, slide along the plane, *A-B*. This is also true of the concrete structure (including the anchoring wall) and the superimposed water load. The resistance to sliding of these several elements is represented by the product of their weight multiplied by the coefficient of frictional resistance.

2.—The foundation material lying between *B-C* and *B-E* must, in case of the failure of the dam by sliding, move simultaneously down stream and upward along the plane, *B-E*. Such movement of this material, therefore, is opposed, not merely by frictional resistance, but also by the force of gravity. The resistance of this particular portion of the foundation material is analyzed subsequently in more detail.

The location of the "planes of least resistance" is dependent on the conditions existing in any particular case. For the conditions shown on Plate XII, a general statement may be made, as follows:

It is evident that, assuming proper design and construction of the anchoring wall at the heel of the dam, the main "plane of least resistance" cannot begin above *A*. Neglecting for the moment the existence of the original cut-off, it is further evident that the main "plane of

least resistance" could not extend downward in a direction such as *A-G*. In other words, the resistance along any plane dipping below the horizontal is necessarily greater than the resistance along the plane, *A-B*. Whether the "plane of least resistance" extends horizontally or in an upward direction from *A* is a matter for determination by trial computation. In this particular case, of course, the old cut-off wall is a factor, even though its effect may be indefinite. For instance, were the break in it to be in an upward direction, such as *A-F*, its effect on the location of the main "plane of least resistance" would be nil, or at least negligible. On the other hand, a break in a downward direction, such as *A-H*, might, owing to the strength of the concrete cantilevering below the elevation of *A*, cause the initial point of the main "plane of least resistance" to be at a lower elevation, for example, at *H* instead of *A*.

To the left of the vertical plane represented by the line, *B-C*, passing through the down-stream edge of the new toe-wall of the dam, the foundation material is confined by the weight of the structure shifted, as it were, toward the down-stream side of the footings by the horizontal thrust of the water load. In effect, this weight is greatest per square foot at the very down-stream edge of the toe-wall, which is practically monolithic with the original structure. The line or plane of failure could not turn upward (from the main "plane of least resistance") on the left side of *B-C* unless the foundation material underlying the dam, and above such new and increased slope, were to fail in compression, or were to "flow".

Moreover, at the toe there is a concentration or transfer of horizontal thrust into the foundation material. In the present instance this transfer of thrust is accomplished partly through frictional resistance between the soil and the toe-wall (especially the horizontal leg thereof), and partly through direct bearing of the toe-wall (especially the vertical leg thereof) against the soil.

It is probable, therefore, that the main "plane of resistance" would end approximately below the down-stream edge of the toe-wall, as at *B*.

If, then, the main "plane of least resistance" is represented by *A-B*, it follows that unless (1) the foundation material fails in compression, as along *B-C*, or (2) the coefficient of frictional resistance is too great, the "plane of least resistance" will turn upward at *B*. Generally speaking, the slope of this plane must be determined by trial,

although, under certain conditions, the slope may be determined by direct computation.

Theory of Resistance at Toe.—The resistance of the foundation material at the toe of the dam, by which, on Plate XII, for instance, is meant the material to the right of *B-C*, is a factor sufficiently important to warrant more detailed explanation. Practically, on account of the character of the material in question, the results of theoretical analysis represent the actual conditions only approximately. The refinement of such analysis, however, is worth while, because it aids in obtaining a thorough understanding of the case.

The problem is essentially one of "passive thrust". The analysis adopted as applying to the general case is based on the assumptions that:

(*a*) The foundation material, *viz.*, earth, is homogeneous and granular;

(*b*) The material is without cohesion;

(*c*) The coefficient of frictional resistance (being the same as the coefficient of internal friction) $= f$;

(*d*) In case of sliding, failure of the foundation material at the toe will occur along a plane, such as *B-E*;

(*e*) The resistance of the foundation material to compression (as in the vertical plane, *B-C*) is so great as not to be the limiting factor in toe resistance;

(*f*) The load on the foundation material in a vertical plane (such as *B-C*) increases in intensity regularly from zero at *C* to a maximum at *B*;

(*g*) It is necessary to the stability of a granular mass that the direction of the pressure of the portions into which it is divided by any plane should not at any point make with the normal to that plane an angle exceeding the angle of repose, *viz.*, *f*.*

Under the foregoing assumptions, it would appear that, in case of failure of the dam by sliding, a wedge-like section of the foundation material would be forced upward approximately between and along *B-C* and *B-E*. The toe resistance—in other words the resistance to movement on the part of such wedge-like section—depends on whether there is frictional resistance along the vertical plane, *B-C*, such as

* Rankine's "A Manual of Applied Mechanics", 17th Ed., p. 213, Theorem I.

there is along the inclined plane, *B-E*. There appears to be no valid objection to the assumption that the resistance along the vertical plane is equal to that along the inclined plane. However, the results will be stated on each basis, the more conservative assumption being that there is no frictional resistance in the vertical plane, *B-C*:

Condition I.—Without friction in the vertical plane, *B-C*. (See Fig. 20.)

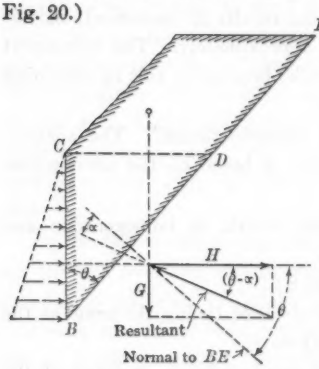

FIG. 20.

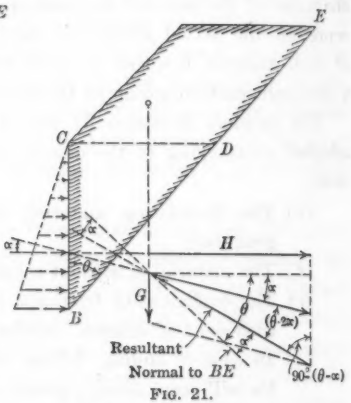

FIG. 21.

If H = horizontal pressure in the plane, *B-C*, against the wedge of earth, *C-B-E*, sufficient to cause movement of the wedge;

G = weight of material (per unit length of dam) included between *B-C* and *B-E*;

α = angle of friction (*viz.*, the angle the tangent of which is f);

θ = angle between "plane of least resistance", *B-E*, and the vertical (plane *B-C*).

Then $H = G \cot. (\theta - \alpha)$, since the friction along the plane, *B-E*, resists both the thrust, H, and movement of the weight, G.

For the purpose in question, it is necessary to determine the minimum value of H. In the general case, with an irregular surface boundary between *C* and *E*, it is necessary to determine such a minimum value by trial. Ordinarily, this can most easily be accomplished by plotting a curve with values of θ as abscissas, and corresponding computed values of H as ordinates. The lowest value of H shown by such a curve is, of course, the desired value.

However, in the special case in which the upper bounding surface is horizontal—as represented on Plate XII and Fig. 20 by *C-D*—the minimum value of H may be stated mathematically by expressing G in terms of θ and then placing the first differential of the resulting equation equal to zero. Accordingly, it is found that H is a minimum when

$$\theta = 45° + \frac{\alpha}{2}.$$

Evidently, in this special case the critical value of θ (giving the minimum value of H) cannot be less than 45 degrees.

Condition II.—The frictional resistance in the vertical plane, *B-C*, equals f. (See Fig. 21.)

In the general case, under this condition,

$$H = G \cos. \alpha \frac{\cos. (\theta - \alpha)}{\sin. (\theta - 2\alpha)}$$

It follows that, since H becomes infinitely great when sin. $(\theta - 2\alpha) = 0$, θ must be greater than 2α. Again, under ordinary physical conditions, G and, hence also, H, become infinitely great for $\theta = 90$ degrees. Therefore, excepting for failure in compression, failure cannot occur unless α is less than 45°—in other words, unless f, the tangent of α, is less than 1.0.

In the special case where the upper surface of the toe material lies in the plane, *C-D*, the minimum value of H may be determined mathematically, as under Condition I, it being found that H is a minimum when

$$\theta = \tan.^{-1}\left(\frac{2 \tan. \alpha + \sec. \alpha \sqrt{2}}{1 - \tan.^2 \alpha}\right)$$

Actual Toe Resistance.—Under many, if indeed not under most, foundation conditions, the toe resistance is limited practically, not by the theoretical minimum values of H as expressed in the foregoing paragraphs, but by a third condition, namely, the bearing value of the foundation material. This is the case at the Stony River site. For design purposes, the maximum load in the plane, *B-C*, under the conditions illustrated on Plate XII, was limited to the safe bearing value, in lateral compression, of the soil at the site. This value was assumed as 4 000 lb. per sq. ft. In other words, the average resistance to sliding in the vertical plane, *B-C*, was limited to 2 000 lb. per sq. ft.

To illustrate the possibilities of toe resistance, as well as the probable actual values, reference is again made to the typical section of the strengthened structure at Bay 35, as shown on Plate XII, all calculations being based on normal maximum load conditions, with f assumed $= 0.33$:

Assuming first that the main "plane of least resistance" to sliding is horizontal (see *A-B*, Plate XII), and assuming that there is no frictional resistance in the vertical plane, *B-C*, the inclined "plane of least resistance" at the toe is found to make an angle, θ, of 44° with the vertical for the minimum value of H (toe resistance to sliding). The corresponding total resistance to sliding is approximately 140 080 lb. per lin. ft. If, instead, the frictional resistance in the vertical plane, *B-C*, is assumed to be equal to that in the inclined "plane of least resistance", the latter is found to make an angle of 67° with the vertical, with a corresponding total resistance of about 183 530 lb. per lin. ft. However, if limited by the assumed safe bearing value of the soil in lateral compression, that is 4 000 lb. per sq. ft., the total resistance to sliding is only 115 080 lb. per lin. ft.

Assuming now at random a different location of the main "plane of least resistance", *viz.*, *A-I* (Plate XII), making an angle, β, of 6° with the horizontal, it is found that, without frictional resistance in the vertical plane, *I-C*, the angle, θ, is 39°, and the total resistance to sliding is about 131 200 lb. per lin. ft.; that with full frictional resistance ($f = 0.33$) in the plane, *I-C*, the angle, θ, is 65°, and the corresponding total resistance is 159 300 lb. per lin. ft.; but that, if limited by the safe bearing value of the soil, the total resistance is only 121 650 lb. per lin. ft. In order to determine the minimum values of the total resistance to sliding for each of the three conditions just mentioned, enough different locations of the main "plane of least resistance" were assumed, and corresponding calculations were made, to warrant the plotting of a diagram in which the values of β (the angle which the main "plane of least resistance" makes with the horizontal) and of total resistance to sliding, respectively, were plotted as rectangular co-ordinates.

It was evident from inspection of the results that, with the resistance at the toe limited by the safe bearing value of the soil, the minimum total resistance to sliding is afforded when the main "plane of least resistance" is in the horizontal position, *A-B*. However, from

the diagram which was based on the assumption that there is no frictional resistance in the vertical plane, β was found to be approximately 8° for the minimum value of total resistance to sliding, equaling about 128 500 lb. per lin. ft. Correspondingly, a value of 8° 15′ was found for β under the assumption that the coefficient of frictional resistance in the vertical plane too is 0.33, the minimum total resistance to sliding being approximately 152 700 lb. per lin. ft. Both these values of total resistance to sliding are greater than that obtained when the resistance at the toe is limited by the safe bearing value of the soil, *viz.*, 115 080 lb. per lin. ft. Consequently, for design purposes, the "planes of least resistance" under "normal maximum load" for the section shown on Plate XII were assumed to be represented by *A-B* and *B-C*.

It is interesting to note to what extent the total resistance to sliding at Bay 35 was increased in the reconstruction. Retaining still the "normal maximum load" conditions, and with resistance at the toe limited by the safe bearing value of the soil, the total resistance to sliding was increased from approximately 41 310 lb. per lin. ft., in the case of the original structure, to approximately 115 080 lb. per lin. ft., in the case of the strengthened structure. In other words, the total resistance to sliding was increased by about 178 per cent. Correspondingly, on the basis of the assumption that the resistance at the toe is not limited by the safe bearing value of the soil, but that no frictional resistance exists in the vertical plane at the toe, the total resistance to sliding would be increased by about 211%; and if, in addition, the coefficient of frictional resistance in the vertical plane is assumed to be 0.33, the increase would have been about 270 per cent.

Of course, there is undoubtedly a considerable difference between theoretical and actual conditions. Thus, referring to the foregoing assumptions on which the theoretical analysis has been based, earth is rarely, if ever, strictly homogeneous. The coefficient of frictional resistance varies, and the "planes of least resistance" are probably never true planes. Crude experiments made by the writer indicate that, even in the case of such granular material as sand, the surface along which failure occurs is by no means a true plane. Under the Stony River conditions, the "planes of least resistance" are affected also by boulders. Again, any cohesion existing within the founda-

tion soil causes the resistance to sliding to be greater than according to the preceding analysis. It is evident, however, that procedure along the lines indicated is amply conservative and safe.

It may not be amiss to point out that anchoring walls such as those described may be applied properly and economically in the case of rock foundations, particularly when the foundations consist of laminated rock with relatively low frictional resistance. By this means a considerable quantity of the foundation rock can be made to afford resistance to sliding just as reliably as though the corresponding weight consisted of concrete in the body of the dam. Generally speaking, anchoring walls, even if not used for the purpose of reducing the quantity of material in the body or superstructure of a dam, will, at least, increase the margin of safety.

Stability of Strengthened Structure Against Sliding.—The design of the features entering into the strengthening of those portions of the dam which remained intact conformed as closely as practicable to the general criterion that the ratio of the probable forces resisting sliding should be twice the probable forces tending to cause sliding.

It will be noted from Plate XII that an earth fill has been placed down stream from the typical section there shown. Fig. 22 shows more clearly the limits and height of this fill, which extends along the entire length of the higher sections of the dam, *viz.*, between the old and the new spillways. Referring again to Plate XII, it is evident that the presence of this earth fill increases the quantity of material lying within the angle, θ. Moreover, the greater the coefficient of frictional resistance of the foundation soil, the greater the angle, θ, and hence the greater the effective resisting weight due to the earth fill. The material for the fill was obtained largely from the excavation for the new spillway channel.

As in the case of the original structure, the margin of safety resulting from the work of strengthening will be illustrated by several examples under different sets of conditions. Thus, for the strengthened sections of maximum height, the results are as follows:

I.—Under the assumed "normal maximum load" conditions, as set out in Column (6), Table 3,

$$\frac{\text{Forces resisting sliding}}{\text{Forces tending to cause sliding}} = 2.03.$$

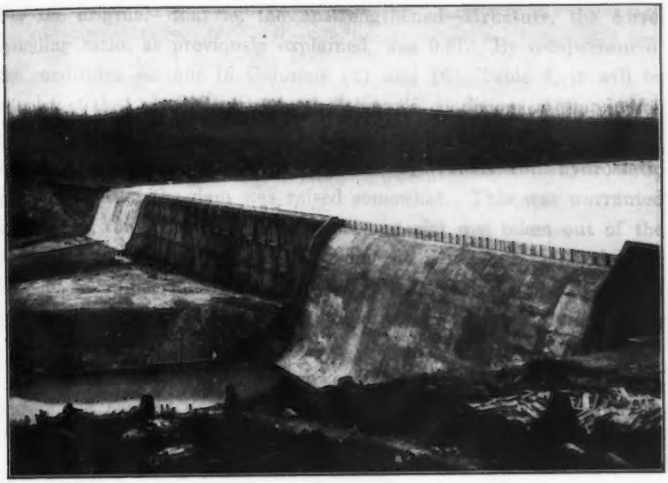

FIG. 22.—STONY RIVER DAM AS RECONSTRUCTED. VIEW FROM WEST BANK.

FIG. 23.—EROSION UNDER FOOTING AT HEEL OF DAM.

For the original—that is, the unstrengthened—structure, the corresponding ratio, as previously explained, was 0.61. By comparison of the conditions set out in Columns (2) and (6), Table 3, it will be noted that the only difference in the assumed conditions is that in the case of the strengthened structure, Column (6), factor (*c*), the assumed elevation of the lower limit of equivalent full hydrostatic pressure against the dam was raised somewhat. This was warranted by the fact that considerable pervious material was taken out of the river-bed, immediately up stream from the dam, and replaced by a back-fill of impervious clay, the back-fill in turn being covered in part with a reinforced concrete protecting mat, especially near the sluice-gates (see Plate XI).

II.—Under the "most severe conditions within the limits of reason", as applied to the strengthened structure (see Column (8), Table 3),

$$\frac{\text{Forces resisting sliding}}{\text{Forces tending to cause sliding}} = 1.07.$$

This ratio is to be compared with the ratio of 0.22 for the sections of maximum height, of the structure as it stood originally. The comparison is the more striking when it is noted that, inasmuch as 3-ft. flash-boards can be used safely on both spillways of the reconstructed dam, the assumed elevation of head-water is 3 ft. greater in the case of Column (8) than in the case of Column (4), which correspondingly sets out the "most severe conditions within the limits of reason" for the sections of maximum height of the original structure.

As to the typical strengthened section at Bay 35, shown on Plate XII, the margin of safety against sliding is represented as follows:

III.—Under the "normal maximum load" conditions set out in Column (7), Table 3, the ratio of safety is 2.14.

IV.—Under the "most severe conditions within the limits of reason", as set out in Column (9), Table 3, the ratio of safety is 1.12.

These ratios, of course, would be bettered by any increase in the respective coefficients of frictional resistance assumed. There are, however, certain additional factors, tending toward greater safety against sliding, which apply in the case of the strengthened portions

of the dam founded on the clayey over-burden, but in none of which was any specific reliance placed, namely:

(*a*) In the structure as strengthened there is no tendency to break at the top of the cut-off wall. The resistance of the old cut-off wall to shear or rupture at the bottom of the new "heel" is, therefore, a considerable factor in resisting sliding.

(*b*) Again, if such shear or rupture in the cut-off wall should occur below the bottom of the "heel", or should extend below the bottom of the "heel" in a direction such as *A-H*, Plate XII, the effect would be to lower still further the "planes of least resistance" and, consequently, to increase the resistance to sliding.

(*c*) The existence of cohesion or resistance to shear in the clayey foundation soil is by no means speculative even though the amount of such resistance may not be readily and reliably determinable.

Tests of Shearing Value of Clay.—The writer has found no previously published data on this subject, and therefore believes that certain tests made during the Stony River reconstruction by Mr. D. N. Showalter, Resident Engineer, will be of general interest. The apparatus contrived by Mr. Showalter for making the test was simple and yet quite effective.

Specimens of clay were dug out of the foundation over-burden and cut to such shape as to fit the apparatus. The shearing was then accomplished by slicing off the clay, as it were, with a 2 by 6-in. piece of wood which was forced across the specimen by a small set of blocks and tackle. The tension in the rope was measured by a spring balance. The specimens tested were fairly moist. The results of these tests of the shearing values of several different clayey soils are given in Table 4.

From inspection of the data in Table 4, it will be noted that, as was to be expected, the presence of sand in the clay very materially lessens the shearing value. However, even among Specimens 1 to 8, inclusive, there is considerable variation among the results. The effect of the length of time of application of a given shearing load was not investigated, though time is undoubtedly a very important

factor. The results clearly indicate that here is a fruitful field for further experimentation.

TABLE 4.—RESULTS OF TESTS OF SHEARING VALUE OF FOUNDATION SOILS AT STONY RIVER DAM SITE.

Experiment No.	Character of soil under test.	Initial area under shearing stress, in square inches.	Load* at failure, in pounds.	Shearing value, in pounds per square inch of initial areas.
1	White clay.	9.0	109	12.1
2	" "	4.8	128	26.6
3	" "	6.1	126	20.7
4	" "	8.7	226	26.0
5	" "	7.7	176	22.8
6	Black gumbo.	19.2	184	9.6
7	" "	19.2	309	16.1
8	Black loam.	13.7	219	16.0
9	Sandy yellow clay.	19.2	89	4.6
10	" " "	14.6	39	2.7
			Average.....	15.7

* Including proper allowance for weight of apparatus.
NOTE.—All soil was in natural state of moistness.

To the writer, it appears that it is hardly proper, in the light of present information, that the shearing value of clay should be taken into account over and above the resistance to sliding developed under such conditions as obtained in the tests of frictional resistance reported in Table 2. The resistance of the clay to shear, however, affords an added margin of safety, indefinite though the extent of the added margin may be. Accordingly, it is interesting to consider what might be the effect of such resistance to shear in a typical case, for example, the section at Bay 35 under "normal maximum load" conditions.

Referring to Plate XII, it will be remembered that, in case of failure of the dam by sliding, it was assumed that failure along *A-B* would occur by sliding of clay on clay, and that failure along *B-C* would occur by the crushing of the clay or other foundation material. Hence it is only along *A-B* that the resistance of the clay to shear could increase the total resistance to sliding. Such resistance to shear, however, would act instead of, and not in addition to, the frictional resistance along *A-B*, which, under the assumed conditions, is about 75 000 lb. per lin. ft. of dam. The average shearing value shown by the tests reported in Table 4 is 15.7 lb. per sq. in. If, then, a resistance to shear of 15 lb. per sq. in., for instance, existed in the

53.5 lin. ft. of clay along *A-B*, the total resistance along *A-B* (exclusive of resistance to rupture on the part of the old cut-off wall) would be about 115 000 lb. per lin. ft. of dam. Thus the total resistance to sliding would be increased by about 40 000 lb. per lin. ft.

However, for the reasons stated previously, and because of the varying characteristics of the foundation soil, resistance of the clayey soil to shear was not relied on to furnish resistance to sliding.

Resistance to Sliding at New Spillway.—Turning now to the new spillway section, as shown on Plate X, it will be noted that, by reason of the use of the combined anchoring wall and cut-off at the heel of the structure, the principal "plane of least resistance" (at the elevation of the bottom of the anchoring wall) lies in relatively hard shale. Free from the hampering conditions imposed by a structure already existing on the site, it was possible at this particular place to secure more readily and economically given ratios of safety than obtain in those portions of the dam which were left intact after the failure. Thus the new spillway section has generally a greater margin of safety.

I.—Referring to the 15-ft. wide section centering on Buttress 17 (Plate IX), the ratio of safety against sliding under the "normal maximum load conditions" is 3.69. The conditions assumed in arriving at this ratio were essentially like those of Column (6), Table 3, except that, in accordance with Table 1, the coefficient of frictional resistance was assumed to be 0.5.

II.—For the same location in the new spillway, but under the "most severe conditions within the limits of reason," the ratio of safety against sliding is 2.03. In this case the assumed conditions were essentially like those of Column (8), Table 3, except that

(*a*) Head-water was assumed at Elevation 142.25, with no ice pressure; and

(*b*) The minimum coefficient of frictional resistance, in accordance with Table 1, was assumed as 0.40.

It is pertinent at this point to note, by reference to Plate XII, that apparently no harm would result from uplift pressure exerted along the planes of contact between the footings of the strengthened structure and the foundation soil. That is, there would be practically no change in the vertical load above the probable "plane of least resist-

ance", such as *A-B*. Likewise, referring now to Plate X, it would appear that uplift pressure could exist in the laminations of the foundation shale rock immediately under the buttress footings (but above the elevation of the bottom of the anchoring wall) without affecting materially the stability of the new spillway section as regards sliding. Such uplift, however, would have a material effect on stability as regards overturning.

Resistance to Overturning.

In the case of a hollow dam with a deck slope of approximately 45° from the vertical, it is hardly necessary to inquire deeply into the question of stability as regards overturning. This will be apparent from the following illustrations:

I.—In the case of the typical section at Bay 35, in its original, unstrengthened condition (see unshaded portion of Section *B-B*, Plate XII), the ratio of safety against overturning under the assumed "normal maximum load" conditions of Column (3), Table 3, was 3.65.

II.—For the same section under the "most severe conditions within the limits of reason", as set out in Column (5), Table 3, the corresponding ratio of safety was 1.14.

In deriving these ratios, moments were taken about the point, *O*, at the toe of the original structure, as indicated in Section *B-B* of Plate XII, and it was assumed that, should the dam begin to overturn, the original cut-off wall would fail at the construction joint at the top of the wall. Furthermore, the horizontal thrust was considered to be taken up entirely by frictional resistance along the base of the footings; that is, no resistance to horizontal thrust was attributed to the body of the cut-off wall. In the second of the foregoing sets of assumptions cognizance was taken of the fact that, in severely cold weather, the weep-holes in the footings of the original structure would have frozen up solidly and become ineffective. Consequently, uplift pressure was considered as affecting a portion, assumed to be 50%, of the total area of the base.

Referring now to the typical strengthened structure at Bay 35, as shown on Plate XII:

III.—The ratio of safety against overturning under the assumed "normal maximum load" conditions of Column (7), Table 3, is 4.57.

IV.—Under the "most severe conditions within the limits of reason", Column (9), Table 3, the corresponding ratio becomes 1.68.

In developing the last two ratios it was assumed, as before, that in case of actual overturning, the original cut-off wall would fail at the construction joint at the top of the wall. However, as regards the effect of frictional resistance along the base of the main footings of the dam, in taking up horizontal thrust, such resistance was assumed to be equal to only 0.2 of the total concrete and water load, the remainder of the horizontal thrust causing a uniformly distributed load on the anchoring wall at the heel. The anchoring wall at the toe was assumed to carry no load. Such assumed distribution of the resistance to the horizontal thrust is obviously arbitrary, but affords the most unfavorable conditions as regards stability against overturning. The resultant of the assumed load on the "heel" would necessarily act at half the depth of the "heel".

Needless to say, the increased ratios of safety against overturning in the case of the strengthened structure were not sought after *per se*. They resulted from the provision made to increase the margin of safety against sliding.

Footings.

Bearing Value of Foundation Soil.—In the case of clayey soil, compressive loading causes appreciable yielding; hence the safe loading or bearing value is measured by the maximum allowable yielding. As the result of observations made at the dam site, under various conditions during the investigation period, and also of various tests of the soil at the site, it was concluded that the yielding due to a compressive loading of about 5 000 lb. per sq. ft. would not exceed 0.1 in. provided the soil is confined against "flow".

It was considered preferable not to exceed a maximum loading of 4 000 lb. per sq. ft., but somewhat greater loads were allowed for the horizontal bearing of the anchoring walls at heel and toe, where the soil is well confined, and also for the footings at the eastern portion of the dam, where the foundation material is of manifestly better character.

The results of the foregoing tests of the safe bearing value of the soils at the site are given in Table 5. The following comments apply to the table:

1.—The variations among the results are characteristic of the foundation soils in question.

2.—In view of the fact that the areas under load in the several tests were very small, it is reasonable to assume that under the actual conditions of loading the foundation soil would show less yielding for a given load. Generally speaking, the more confined the soil under compression, the less its yielding under load, and hence the higher its safe bearing value; furthermore, the greater the area under compression, the greater the proportion of the stressed soil which is confined against "flow".

3.—In general, the foundation soil of the east bank at the dam site has a higher bearing value than that of the middle of the valley, or of the west bank.

Loading of the Foundation Soil.—Calculations as to the loading of the foundation soil were based on the assumption that where the cut-off, whether in its original state or underpinned, is of relatively great depth, and especially where it extends down to bed-rock, the cut-off wall forms a relatively rigid, unyielding support for the dam; whereas the foundation soil down stream from the cut-off forms a yielding support. For practical purposes, therefore, it has been assumed that, when under load, the dam pivots about the top of the original concrete cut-off wall, the cut-off and the foundation soil down stream therefrom each carrying its due proportion of the total vertical load. The axis about which the dam is assumed to pivot is approximately in the plane of the base of the original footings. Following this assumption further, it is evident that the deflection in the foundation soil would vary approximately uniformly from zero at about the center of the cut-off wall to a maximum at the down-stream edge of the toe of the dam.

There is, of course, a certain amount of flexibility in the concrete footings; that is, the true deflection (and hence stress) diagram of the soil underlying the structure would not be a straight line. However, the effect of such flexibility in the footings is indeterminate, and the straight-line assumption was adopted in computations.
